MARCH 1976

# THE AMERICAN ECONOMIC ASSOCIATION

Founded in 1885

• Published at George Banta Co., Inc., Menasha, Wisconsin.

• THE AMERICAN ECONOMIC REVIEW, including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory*, and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December.

Association membership dues for 1976, which include a subscription to both The *American Economic Review* and the *Journal of Economic Literature*, are as follows:

$25.00 for regular members with rank of assistant professor or lower, or with annual income of $12,000 or less;

$30.00 for regular members with rank of associate professor, or with annual income of $12,000 to $20,000;

$35.00 for regular members with rank of full professor, or with annual income above $20,000;

$12.50 for junior members (registered students). Certification must be submitted yearly.

Subscriptions (libraries, institutions, or firms) are $37.50 a year. Only subscriptions to both publications will be accepted. Single copies of either journal may be purchased from the Secretary's office, Nashville, Tennessee.

For foreign postage, add: PUAS countries, $2.10; all other countries and Canada, $2.50.

• Correspondence relating to the *Papers and Proceedings*, the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address should be sent to the Secretary, C. Elton Hinshaw, 1313 21st Avenue South, Nashville, Tennessee 37212. Change of address must reach the Secretary at least six (6) weeks prior to the month of publication. The Association's publications are mailed second class.

• Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

# THE AMERICAN ECONOMIC REV

March 1976

VOLUME 66, NUMBER 1

• Manuscripts and editorial correspondence relating to the regular quarterly issue of this REVIEW should be addressed to George H. Borts, Managing Editor of THE AMERICAN ECONOMIC REVIEW, Brown University, Providence, R.I. 02912. Manuscripts should be submitted in duplicate and in acceptable form and should be no longer than 50 pages of double-spaced typescript. A submission fee must accompany each manuscript: $15 for members; $30 for nonmembers. *Style Instructions* for guidance in preparing manuscripts will be provided upon request to the editor.

• No responsibility for the views expressed by authors in this REVIEW is assumed by the editors or the publishers, The American Economic Association.

# Rigor and Relevance in a Changing Institutional Setting

By Robert Aaron Gordon*

The title of this paper summarizes the two-fold theme to which I want to address myself this evening. First, the mainstream of economic theory sacrifices far too much relevance in its insistent pursuit of ever increasing rigor. And, second, we economists pay too little attention to the *changing* institutional environment that conditions economic behavior. We do not often enough reexamine our basic postulates in light of changes in this environment, and, perhaps more important, we shy away from the big questions about how and why the institutional structure is changing—and where it is taking us.[1]

## I

Economists pride themselves on belonging to the most "scientific" of the social sciences. The justification for this contention lies in the growing resemblance between the nature of the analytical tools used in economics and in the natural sciences—above all, the increasing use of mathematical tools in theoretical analysis and the development of sophisticated mathematical and statistical techniques in empirical work. Today, mathematically formulated economic theory, the development of econometric techniques, and the sophisticated application of econometric methods to the "testing of hypotheses" in a variety of applied fields constitute the core of the science of economics.[2]

What is science? One brief definition runs: "A systematic knowledge of the physical or material world." Most definitions emphasize the two elements in this definition: (1) "systematic knowledge" about (2) the real world. Without pushing this definitional question to its metaphysical limits, I merely want to suggest that if economics is to be a science, it must not only develop analytical tools but must also apply them to a world that is now observable or that can be made observable through improved methods of observation and measurement. Or in the words of the Hungarian mathematical economist János Kornai, "In the real sciences, the criterion is *not* whether the proposition is logically true and tautologically deducible from earlier assumptions. The criterion of 'truth' is, whether or not the proposition corresponds to reality" (p. 9, his italics). (Compare Wassily Leontief 1966, p. 23.)

One of our most distinguished historians of economic thought, George Stigler, has stated that: "The dominant influence upon the working range of economic theorists is the set of internal values and pressures of

* Presidential address delivered at the eighty-eighth meeting of the American Economic Association, Dallas, Texas, December 29, 1975. My thanks for helpful suggestions go to Moses Abramovitz, G. L. Bach, John Gurley, and Benjamin Ward. And being uninhibited by virtue of their membership in the same family, Margaret S., David M., and Robert J. Gordon not only offered suggestions but forced me to rewrite substantial sections through successive drafts. Finally, I want to thank James Hodder and Carl Walsh for their assistance, which was made possible by the Institute of Industrial Relations, University of California, Berkeley.

[1] A number of economists have anticipated various of the points made in this paper, and some are cited later. In addition, I should mention E. H. Phelps Brown and G. D. N. Worswick. And there are others, several of whom were cited by Walter Heller in his presidential address last year.

[2] I trust that noneconometric applied economists, including Nobel prize winner Simon Kuznets, will forgive me for thus excluding them from the "core" of economics.

the discipline. The subjects of study are posed by the unfolding course of scientific developments" (p. 22). He goes on to add: "This is not to say that the environment is without influence. . . . " But, he continues, "whether a fact or development is significant depends primarily on its relevance to current economic theory" (p. 23). (Compare Tjalling Koopmans, p. 170.) What a curious relating of rigor to relevance! Whether the real world matters depends presumably on "its relevance to current economic theory." Many if not most of today's economic theorists seem to agree with this ordering of priorities.[3]

To what aspects of the observable world does economics apply its analytical tools? According to the familiar definition in the *International Encyclopedia of the Social Sciences*, which we owe originally to Lionel Robbins, economics "is the study of the allocation of scarce resources among unlimited and competing uses." To this definition of microeconomics the *Encyclopedia* then rather weakly adds macroeconomics, which is defined as the study of money, the general price level, and the level of output and employment.

Let us consider the microeconomic part of this definition. Presumably the reference is to real resources, used to produce observable goods and services, that are exchanged and consumed by real people living in the kind of world we see around us. Of course, some degree of abstraction is necessary if useful generalizations are to be reached. Here the economic theorist quickly runs up against a dilemma. Shall he seek to make his analysis ever more rigorous, regardless of the possibly diminishing relevance of his conclusions to the observed world? Or shall he sacrifice elegant refinement for somewhat cruder analysis that may lead to testable results? I suppose the reply can be given that we need to do both and that we need specialists in each of these approaches. But certainly those who construct the analytical apparatus should pay more attention than many of them now do to the substantive problems with which economists are presumably concerned.[4]

In speaking of how well current microeconomic theory combines rigor and relevance, I should distinguish among the different but interrelated problem areas with which this part of economic theory concerns itself. Micro theory addresses itself primarily to three related topics: (1) the conditions necessary for, and the means of actually achieving, an optimum allocation of resources *within* decision-making units, both firms and households, under given assumptions as to the criteria of optimization; (2) again under given assumptions, the conditions necessary for the existence of a general (or partial) equilibrium among all (or some) of these decision-making units, including the determination of the uniqueness and stability of such an equilibrium; and (3) the conditions required for the achievement of an economic optimum from a broad, social point of view.

Some success has been achieved in blending rigor and relevance in the theory of the single decision-making unit. Certainly, as this year's Nobel prize in economics attests, considerable progress has been achieved in dealing with production planning in the individual firm or establishment (or government department) for which mathematical tools, including programming and the whole range of activity analysis, have proved to be useful. To some extent, how-

[3] This has led Leontief to expostulate: "Seldom, in modern positive science, has so elaborate a theoretical structure been erected on so narrow and shallow a factual foundation" (1966, p. 33). Compare also Nicholas Kaldor, p. 1240, and Martin Shubik (1970).

[4] For a careful and judicious defense of theoretical models, see Koopman's second essay. He also adds: "Precision and rigor in the statement of premises and proofs can be expected to have a sobering effect on our beliefs about the reach of the propositions we have developed" (p. 147).

ever, the success achieved here makes this part of economics resemble more a branch of engineering than a social science. And at the level of the individual firm some progress continues to be made in empirical studies of production and cost functions, the determinants of the demand for inputs, the transmission of technical change, and related topics. I do not wish to minimize the value of this work. But we should not ignore the extent to which rigorous formulations of the theory of the firm have had to be relaxed in order to obtain useful results in empirical work. Nor, I might add, should we forget the extent to which conventional theory ignores how and why work is organized within the firm and establishment in the way that it is, what may be called the "social relations" of the production process.

Some success in blending rigor and relevance has also been achieved in the field of household behavior—ranging from studies of the determinants of consumers' demand to recent work on human capital, the behavior of labor markets, the economics of crime, and the like. I must confess to some skepticism, however, about the relevance of the economic models of household behavior recently developed by Gary Becker and his followers—what has been referred to as "the new home economics." Granted that much useful work has been done in this area. Nonetheless there is a lamentable tendency among scholars in this field to rely upon a caricature of human beings who continuously and consciously balance costs and benefits at the margin, whether in deciding on another year of schooling, whether and when to marry or be divorced, how many children to have and when, or whether and when to commit a crime. And after a substantial amount of intensive research, the human capital approach still leaves unexplained a significant part of the differences in personal incomes.

In the second area mentioned, particularly general equilibrium theory, it seems to me that relevance has been largely absent in the recent literature. To find much relevance at the theoretical level, and I refer here only to the theoretical literature, we must go back to the partial-equilibrium analysis of Alfred Marshall and his followers. Walras, Pareto, and their successors—with their assumptions of atomistic competition, perfectly flexible prices, costless information, and limitless futures markets—have contributed little to relevance in their steadfast pursuit of rigor. Although a step in the right direction, recent attempts to develop a pure theory of disequilibrium are subject to much the same criticism.

Rigor and relevance have been successfully blended in input-output analysis, although largely at the expense of ignoring the price sensitivity of input-output coefficients. Here again, the emphasis is on engineering-type relationships, but in this case the entire economy is the object of study.

Micro-economic analysis, as I have noted, concerns itself with "the allocation of scarce resources among unlimited and competing uses." As economists we are concerned with how resources may be allocated *efficiently*, and we are prepared to provide the layman and the policymaker with a rigorous definition of efficiency. But "efficient allocation" for whose benefit? To me it has always been startling that the accepted province of micro-economic theory has little room for the personal distribution of income—and virtually none for the personal distribution of wealth. Of course, we speak of "distribution," but by this we mean either factor prices or total factor shares.

Why wealth and labor services, the latter carrying widely different market-determined prices, are distributed among different human beings in the way they actually are is a question that the non-Marxian

economic theorist seldom asks. An exception should be made for the relevant literature in the field of labor economics. Similarly, some exception should be made for the recent literature on human capital, but at best it is only a partial exception.[5] The mathematically inclined general theorist continues to show little interest in the determinants of the personal distribution of income and wealth.[6] It has been said by George Stigler that: "The problem of personal income distribution will eventually receive much theoretical attention, since it is a problem of all economies and all times" (p. 22). (Compare Becker, p. 135.) But if the problem is so important, why only "eventually"? It is not surprising that many younger economists are seeking a radical alternative for the neoclassical framework, more or less along Marxian lines. And it is also this concern with the unequal personal distribution of opportunity and income which has led to the development of models of a dual labor market. These models, with their emphasis on institutional barriers to labor mobility, offer some valuable insights into the operation of contemporary labor markets, and they also raise important questions about some of the assumptions implicit in neoclassical theory.[7]

From the point of view of human welfare—a concept that will not go away no matter how uncomfortable it makes the economic theorist—can we ignore the personal distribution of income? Which is more relevant: a rigorous demonstration as to how resources can be most efficiently allocated under ideal conditions that have never existed, or a much cruder exploration of how wealth and income came to be distributed as they in fact are and what might be done to affect the distribution of income in one way or another? As Alice Rivlin put it in her Ely lecture last year (p. 2), economists "worth their pay" ought to be able to explain the shape of the income distribution and why it is changing or not changing. By this criterion very few of us are worth our pay.[8] To go further, why do we have so little to say about the intergenerational movement among occupational and income classes, about the determinants of the distribution of income relative to those affecting the distribution of wealth, and about the ethnic, social, political, and regional factors affecting the distribution of both wealth and income?

Am I suggesting that economic theory become much more normative than it now is? Of course I am not. "Relevant" and "normative" are not synonyms, and what I am alleging here is that neoclassical economics has failed to be relevant in its refusal to deal with the personal distribution of income and wealth. This refusal stems, I presume, from the fact that, with the analytical tools at hand, the problem has seemed too difficult.

I should add in this connection that neoclassical economics has always had a normative slant. As others have suggested,

[5] In the second edition of *Human Capital*, pp. 94–144, Becker republishes his earlier attempt to utilize the human capital approach to sketch out a theory of personal income distribution. See also Jacob Mincer.

[6] On the various approaches to the study of the distribution of income, see the useful volumes by Martin Bronfenbrenner and Jan Pen. Interestingly, some three-quarters or more of Bronfenbrenner's book is devoted to the functional distribution of income; only one chapter is devoted entirely to "Topics in Personal Income Distribution." Yet one reviewer criticized him, as well as Pen, for devoting too much space "to the distributional influence of institutional forces and to the personal, as against functional, distribution of income" (Charles E. Ferguson, p. 440). Pen's volume contains a useful summary of the more important recent literature on the determinants of the personal distribution of income; and, interestingly, his longest chapter is concerned with "norms and policies" for income redistribution.

[7] Compare Arthur Okun (1973, pp. 237–46) and Michael Wachter and the references there cited. Cairnes and Marshall, of course, did talk about noncompeting groups, but little of this has carried over into the main body of current economic theory.

[8] One who has recently earned his salary is Okun (1975); see also James E. Meade and Alan Blinder. An earlier example of an economist who "bucked the trend" to discuss the personal distribution of income and wealth was Hugh Dalton.

conventional micro-economic theory as it has developed, particularly in the last seventy-five years or so, takes a normative stance by default.[9] Indeed, it takes a normative stance by more than default. It says outright that the primary question to which economists should address themselves is the "optimum" allocation of resources, and it insists on providing a precise definition of optimum. (Compare Ward, pp. 52–54, 90.) Since, as Koopmans points out, competitive equilibrium theory ignores the welfare implications of the personal distribution of income that results, "the term 'optimum' [is] a misnomer" (p. 49). (See also Ward, pp. 197–98.)

My remarks thus far have been directed toward microeconomics. But macro-economic analysis also must face the problem of how optimally to combine rigor and relevance. What we today call macroeconomics grew out of the catastrophe of the Great Depression,[10] and in the early development of macro-economic analysis relevance took precedence over rigor. Today, rigor competes with relevance in macro-economic and monetary theory, and in some lines of development macro and monetary theorists, like many of their colleagues in micro theory, seem to consider relevance to be more or less irrelevant. A good example has been the elaboration of so-called growth theory which now seems to be losing some of its earlier popularity. Apparently, there has come to be a growing recognition that the considerable efforts spent on growth models have not significantly advanced knowledge beyond the contributions of the original Harrod-Domar and the Solow-Swan neoclassical models. And other intriguing topics have arisen to stimulate the pursuit of rigor at the expense of relevance.

In both micro- and macroeconomics, efforts are sometimes made to extract a drop or two of relevance from exercises in analytical rigor; and conclusions are drawn about the functioning of some aspect of the real world, or policy recommendations are made, on the basis of theoretical exercises which rest on assumptions that fly in the face of the facts. One example is the frequent fitting of the neoclassical investment function, with its built-in assumptions of constant returns and perfect competition, to industries in which these assumptions obviously do not hold. Another example is a good deal of the recent literature seeking to reformulate the micro-economic foundations of macro-economic theory and policy—what Edmund Phelps (1969, 1972) has termed "The New Microeconomics in Inflation and Employment Theory." The theoretical analysis in much of this literature rests on assumptions that also fly in the face of the facts. To cite a few examples: all unemployment is a voluntary activity as part of a search procedure in which workers are continuously equating costs and prospective benefits at the margin; the labor supply is typically taken to be homogeneous with perfect mobility among labor submarkets; so-called structural unemployment is ignored as are the striking differences in unemployment rates among different age, sex, ethnic, and occupational groups; and downward wage flexibility is generally assumed, although some recent attempts have been made to relax this assumption. Another related recent development in which theory proceeds with impeccable logic from unrealistic assumptions to conclusions that contradict the historical record, is the recent work on rational expectations. (Compare Robert J. Gordon.) And, as a final illustration I might cite much of the recent literature on capital theory.

## II

I turn now from the first part of my title to the second—from rigor and relevance to

[9] Marxian critics might add that the normative stance results from ideological bias.

[10] To say this is not to minimize the contributions of Keynes' predecessors, particularly Wicksell.

the fact that we live in a world that is continually changing. And here I want to pose two questions: First, to what extent does the changing institutional environment affect the relevance of the analytical tools that we use and the assumptions that we make about the determinants of individual and group behavior? (Here, of course, I am still raising the question of relevance.) And, second, why do we ask so few questions about why and how the institutional environment has changed in the way that it has, and what are its internal dynamics that will lead it to change in particular ways in the future—not only in the United States but in other countries? A few economists have addressed themselves to this range of questions, notably Karl Marx and Joseph Schumpeter. Among living economists, three who at least raise this range of issues are John Kenneth Galbraith, Gunnar Myrdal, and, in the Marxist tradition, Paul Sweezy.[11]

Certainly the outstanding example of the failure of economic theory to adapt its analytical tools to the changing institutional environment must be the stubborn adherence to the assumption of perfect competition, a concept which has been described as being "as pervasive and fundamental as any in the whole structure of classical and neoclassical economic theory" (Stigler, p. 234).[12] Indeed for a century or so, economists have toiled to make more precise the notion of a perfectly competitive market. Over this same period, of course, the character of actual markets has been changing in many ways. While improvements in transportation and communication have tended to promote competition in expanding markets, the growth of large firms and the spread of industrial concentration have made oligopoly a much more relevant model for industrial markets than the perfectly competitive model which today's theorists insist on using. It is true that sporadic efforts have been made to develop a theory of oligopoly, and for a while high hopes were held for what might be learned from game theory; but no generally accepted theory of oligopoly has yet emerged. At the same time, the emphasis on general equilibrium theory has tended to turn attention away from this egregious departure from perfect competition.[13]

It is true, of course, that in the 1930's, under the stimulus of the pioneering works by Edward Chamberlin and Joan Robinson, we developed a theory of monopolistic or imperfect competition, centering on the notion of product differentiation. And at the same time increased attention began to be paid to the determinants of oligopolistic behavior. At the applied level, the field of industrial organization was born. But while this applied field has continued to thrive, general micro-economic theory and the applied work in this area have largely parted company. General equilibrium theory (and not only this branch of theory) has returned to the assumption of perfect competition. The notion of a sloping demand curve for the individual firm seemingly did not add much to the general theorist's tool box, and the new mathematical economics found it more exciting to pick up the challenge of Walras and Pareto and to turn to general equilibrium analysis and to setting forth the conditions of Pareto optimality. And for this the assumption of perfect competition was convenient if not essential. As William Baumol

[11] There are, of course, a fair number of economists who consider themselves to be in the American institutionalist tradition. They are likely to belong to the Association for Evolutionary Economics, which has its own journal, but thus far they have had little influence on the main trends in theoretical and applied work in economics.

[12] See also Schumpeter (1954, pp. 972 ff).

[13] See, for example, the papers by Paul Joskow and Martin Shubik in last year's *Papers and Proceedings* of the American Economic Association. See also Shubik (1970, p. 415), who bluntly declares: "There is no oligopoly theory."

has noted, "The case of product differentiation has proved particularly resistant to general equilibrium analysis" (p. 45).[14]

And so, as power blocs multiplied in a pluralistic world, as firms grew larger and as conglomerates were added to vertical and horizontal combinations, as advertising expenditures mounted to influence spending out of rising discretionary income, as the problem of externalities became ever more important, and as the role of government in the functioning of markets steadily increased, micro-economic theory largely averted its eyes and became ever more enamored of hypothetical systems of general equilibrium under conditions of perfect competition.[15]

In the meantime, instructors in undergraduate micro theory have resolutely continued to teach their students the essentials of the Chamberlinian partial equilibrium analysis, with downward sloping demand curves facing the individual firm, and laying down the conditions for short-run and long-run equilibrium on an industry basis. That much, at least, undergraduates seem able to absorb, and some factual counterparts can be found for the theoretical analysis. But at the graduate level in many universities, and the more so the more advanced the level of instruction, Walras and Pareto and their successors take over, and the analysis proceeds on the basis of the conditions associated with atomistic competition.

A further example, reflecting another dimension of the growth of large-scale business, involves the conditions under which decisions are made in the large firm.[16] Involved here are a number of issues which have been the subject of some theoretical analysis and a good deal of empirical work in the postwar years, but very little of the results of this work has yet found its way into main corpus of micro-economic theory. I have in mind such questions as the relative roles of profit maximizing and of other criteria in the decision rules used in the large firm, the effects of the separation of ownership and management on these optimization criteria, the ways in which the bureaucratization of decision making affects the manner in which business firms respond to market stimuli, and the effect of the improvements in the gathering and processing of information that have come not only from the revolution in data processing but also from the development of a more scientific approach to decision making.[17] What has been the effect of all this on the pricing decisions of large firms, the manner in which they participate in wage negotiations, or how their investment planning responds to current and prospective developments in product and financial markets? And there are other examples of the same sort. Early work not only in

[14] Kenneth Arrow (1971) has since attempted to fit into general equilibrium analysis the case in which there are both monopolistic and competitive firms. I should say that this exercise was characterized more by rigor than by relevance.

[15] I am speaking here only of the persistence of the assumption of perfect competition in theoretical work, regardless of the changes to which I refer. This is not to deny that useful theoretical work has been done in some of these problem areas.

At this point, I cannot refrain from quoting Arrow: "The prestige status of the purest of pure economic theory has never been higher; and yet there is now, as there has always been, a pervasive skepticism about the descriptive power and normative utility of Walrasian and other varieties of the theory of general competitive equilibrium" (1967, p. 733).

[16] Here I emphasize decision making in the *large* firm. Much of the recent theoretical work on decision making under uncertainty has taken place in an institutional vacuum and is presumably applicable to small as well as to very large decision-making units. On the other hand, what is conventionally referred to as organization theory generally addresses itself to the relatively large organization. For an innovative attempt to develop a theory of economic behavior for the large firm, see Robin Marris (1964). In this context, reference should also be made to the work of Richard Cyert, James March, Herbert Simon, and their students at Carnegie-Mellon.

[17] For a survey of some of the relevant recent literature with an emphasis on the institutional setting for decision making, see Eirik Furubotn and Svetozar Pejovich. The issues raised here are also emphasized by Galbraith.

economics but also in the other social sciences led to the development of what is now called "organization theory," and this is now a field in the better business schools; but not much of this has seeped into the mainstream of economic theory.

Some economic theorists today are beginning to pay serious attention to the beginnings of a theory of information, and increasing attention is being paid to problems of decision making under uncertainty. But here again too little attention tends to be paid to the changing conditions under which information is collected and processed, and the manner in which institutional arrangements affect the way in which the future is viewed and attitudes toward uncertainty change.

There is another and indeed startling respect in which pure micro-economic theory tends to ignore the changing institutional environment. This has to do with the steadily increasing role of government in the functioning of markets. In neoclassical general equilibrium theory, there is no place for any kind of public authority. Of course, we have the field of public finance, which on the theoretical side and at the micro level does borrow from neoclassical theory; and, as Walter Heller reminded us last year, cost-benefit analysis and tax-incidence theory have helped economists to develop a rationale for many types of government decision making. There is also a growing literature on the economics of government decision making in a range of problem areas—from pollution to military spending to housing and education. But the pure micro theorist finds no role for a public authority in his analysis of the determinants of general equilibrium. (See Bent Hansen, p. 92.)

Here we encounter an important difference between micro and macro theory. Much of macro theory (but by no means all) tends to be policy oriented and to have a strong normative orientation. It is concerned both with policy variables and with variables that can be, directly or indirectly, influenced by policy. While there is a good deal of macro theory in which the possible role of government is ignored, much of theoretical macroeconomics does, either explicitly or by implication, leave an important role for government.

Although macro-economic theory does not ignore the role of government, we can still find plenty of examples of the failure of macro theory to reflect the changing institutional environment. One of the most striking examples undoubtedly involves what little we have in the way of a theory of inflation. The problem is most acute with respect to accounting for inflationary trends since World War II.

A number of explanations are currently circulating regarding the tendency toward accelerating inflation in the last decade or more. The purely monetarist one is the simplest and makes no reference to a changing institutional structure. It tends to ignore the sources and nature of the pressures, operating through government, which lead to changes in the supply of money. An increasing number of economists, monetarists and Keynesians, emphasize the existence of a natural rate of unemployment, with the implication that government policies to expand aggregate demand, by pushing unemployment to or below the natural rate, lead to accelerating inflation. But advocates of the natural rate hypothesis have little to say about why the natural rate, if it exists, is what it is today, and how and why it has changed over the years. Much of the work in this area tends to be done in an institutional vacuum, including the recent work on the formation of price expectations.

I think it is fair to say that we still lack a general theory with a significant time dimension of the nature of the inflationary process and how this process is affected by the changing institutional setting. Gunnar

Myrdal is one of those to emphasize that "in modern society the tendency of inflation to become cumulative and to accelerate is rooted in a wide and complex institutional reality" (p. 24), and to urge a broader, institutionally oriented analysis of underlying causes and possible remedies. Another is Peter Wiles in a provocative recent essay in the *Economic Journal.* Among these institutional changes making for more rapid and apparently accelerating inflation are the postwar commitment in all advanced countries to a high level of employment (stronger in Europe than in the United States), the reluctance fully to cover increasing public expenditures by taxation, the growing tendency to link wage and other payments to the consumer price index, the increasing aggressiveness of trade unions (emphasized by Wiles) and other organized groups of income receivers, an apparent weakening of the willingness of employers to resist wage demands (which is closely related to the government's commitment to high employment), and the intensification of inflationary expectations engendered by past inflation. (See Myrdal, pp. 23 ff.) To all of which we can add an international monetary system that permitted huge dollar outflows which became expanded monetary reserves for other countries. This is a familiar list. But how do these different but related inflationary pressures interact? Why have they become stronger? How do we account for the particular rate of acceleration that has occurred? Why does the rate of acceleration seem to be different, and because of what differences in the institutional environment, in different countries? And how have the significant changes in the international system of trade and finance affected these inflationary trends? (See R. J. Gordon.)

I shall merely mention one other example of the failure of economists today to take adequate account in setting up their models of the changing institutional environment. This has to do with the determinants of household behavior, with respect to both the demand for goods and services and the supply of labor services. What has been the effect on household behavior, for example, of advancing levels of education, changes in the ways that news is disseminated, recent trends toward urbanization and suburbanization, or the massive change in the impact of advertising made possible by television?[18] To what extent have these and other developments made households behave more or less in the way that economic theory assumes? What bearing do these and other institutional developments have on the behavior of personal saving in recent years, in this and other countries, and on the way that households respond to recent and prospective inflationary trends?

## III

I turn now to my second question about the changing institutional environment. Why does the central body of economic analysis show so little interest in why and how the institutional setting for economic behavior has changed in the past and is likely to change in the future? The past, of course, is the domain of the historian, but I am not aware that the vast amount of historical research in the past century or more has yet given us an acceptable model of socioeconomic development in today's advanced economies. As I put it more than a decade ago, "Contemporary economics does not yet have the tools required for a comprehensive and evolutionary theory of economic behavior that would take appropriate account of the main lines of institutional change" (p. 146).[19] Schumpeter (1947) came closer in this century to pro-

[18] Work has been done in some of these areas, but this work has largely lacked a time dimension.

[19] The next several paragraphs borrow heavily from pp. 138–42 of this paper.

viding such a theory than has any other economist in the more-or-less orthodox tradition. Outside that tradition, we can turn to the Marxian literature.

Here, of course, I am harking back to a major plea of the early institutionalists. Veblen asked long ago, in the title of one of his papers, "Why Is Economics Not an Evolutionary Science?," and Wesley Mitchell urged the need for a comprehensive theory of economic behavior that takes the cumulative change of institutions as its chief concern. The institutionalists themselves did not develop such a comprehensive and evolutionary theory. While the classical writers did have the elements of a dynamic system—what Baumol once referred to as the "magnificent dynamics" of the classical school—they theorized on the assumption of a fixed set of social and economic institutions. As Schumpeter put it, "the classics reasoned in terms of a particular historical situation which they uncritically idealized and from which they uncritically generalized" (1947, p. 75).

As for contemporary economists in the neoclassical tradition, they, like their predecessors, seem to be afraid to ask the really big questions about the economic aspects of society—questions which, because they are big, must be concerned with the changing institutional fabric. Some exception to this generalization should be made for the considerable effort that has gone into the study of the underdeveloped parts of the world. Here economists have not been able to ignore the interaction of the institutional environment and economic behavior, and increasing attention has come to be paid to the conditions necessary for one or another kind of change in that environment. I might add here that I continue to be impressed by the fact that in general economists in the advanced countries seem to be prepared to be more institutional in dealing with other parts of the world than they are in studying the particular societies in which they live and do most of their work.[20]

Might the following conceptual framework provide a basis for a more systematic study of the dynamic interaction of economic behavior and the institutional framework? At the most basic level, a society is composed of individual human beings. These individuals are members of households. The larger number of them sell the factor services they control to producing units ("firms" for short); and those who sell labor services must physically participate in the production process. A flow of newly produced goods and services results. The distribution of these goods and services among potential claimants depends on much more than the operation of "impersonal market forces." It reflects a complex of institutional arrangements, which include, among other things, the distribution of power among different groups to influence particular commodity and factor markets, both directly and through government, how the ownership of wealth is distributed and for whose benefit it is used, the tax structure and network of government regulations that emerge from the political process, and the total and distribution of net claims by the rest of the world against domestic output.

Individuals not only are members of households and suppliers of input services to producing units (which may be governmental as well as private), but they are also part of a political process which, while

[20] Lance Davis and Douglass North have recently set forth a tentative and limited "theory of institutional change" and have applied the resulting model to show how a range of economic needs and opportunities have led to new institutional arrangements in the American economy. They are frank in setting forth some of the limitations of their model, and there is a good deal in their approach with which I should quarrel; but their work is clearly a step in the right direction. Incidentally, this particular approach to economic history tends to run counter to the recent quantitative emphasis in that field. Clearly we need to have both types of historical work.

partly local and regional, culminates in the powers of a national government.

Thus we begin with the households and producing units of conventional economic theory but immediately add government as a third basic unit. Households, firms, and government interact within a set of evolving economic institutions. These economic institutions include a hierarchy of markets for current output and for the services of labor, capital, and natural resources, and an array of supporting institutions—from commercial banks to labor mediators to government agencies—that also make a contribution to total output. Households and firms interact not only in response to the standard market stimuli but also by organizing pressure groups to influence both government and particular markets.

These pressure groups—not only labor unions and trade associations but a wide variety of other formal and informal groups—operate within and are conditioned by an evolving set of political and legal institutions that lay down the ground rules as to the way households, firms, and government interact with each other. A major aim of the pressure groups is to influence government and markets not only directly but also by altering legal and political institutional arrangements. And as a result of these pressures, the conditions under which households and firms carry out their economic functions change with the passage of time—as do the ways in which households and firms, through a variety of forms of organization, seek to change these conditions still further in favor of their particular interests.[21]

[21] My emphasis on pressure groups is, of course, much more pluralistic than the Marxist analysis in terms of classes and class conflict. One can synthesize the two approaches by sorting the pressure groups into (two or more) broad classes. But I think that we have to start with the pressure groups if we want to study the functioning of markets and the dynamic interaction between the private sector and government.

We may speak of households, firms, and government as the primary economic agents which carry on their activities within the framework of a set of evolving economic institutions. But these agents and economic institutions also interact with an external environment which can be classified in a variety of ways. One simple classification might be: (1) the framework of legal and political institutions, to which I have already referred; (2) the complex of social institutions that make up what may loosely be referred to as the social environment; (3) the evolving body of scientific and technical knowledge (and the institutions through which such knowledge is developed and transmitted); (4) the physical environment; and (5) the complex of political and economic arrangements that tie a nation to the rest of the world.

Against this background, let us now come back to my final question about the evolving institutional environment, which bluntly put was: How did we get to where we are, and where are we going? Or, if you will, what is the future of capitalism and of the kind of market economy to which we are accustomed and which is changing before our eyes? Lacking a dynamic, politico-economic, and institutionally oriented model, the neoclassical economist averts his eyes—or possibly, and reluctantly, refers the questioner to the still growing Marxist literature. Has not the time come for "orthodox" economists—both defenders and critics of neoclassical theory—to repair this glaring deficiency? Let us borrow what seems appropriate from Marx and his followers as well as from others, although what Marx had to say fitted nineteenth century England much better than it does late twentieth century Western Europe or the United States. But at least let us try to construct a model of the sort I suggest that will have something to say about the evolution and future of the kind of economy and society in which we live.

Sketchy as it is, and it is certainly sketchy, I think my suggested conceptual framework or something similar offers a possible starting point. And there are many intermediate questions to be raised along the way. We have been witnessing a significant extension of government control of the market mechanism in all of the advanced economies, more so in some than in others. This intervention ranges from conventional forms of regulation of particular industries, to sporadic attempts to impose one or another kind of incomes policy, to large-scale programs to redistribute incomes, to widening experiments in worker participation, to outright nationalization of particular firms or industries. What combinations of pressures have caused this extension of government intervention; what forces will extend it further; what forms will such intervention take; and what are likely to be the effects on the allocation of resources, the distribution of income and wealth, and the rates of inflation and of growth in total output—not to mention the possible effects on the various dimensions of the institutional environment, including the institution of private property?

There are many other elements, besides the few mentioned here, that would have to be incorporated into a full-fledged, institutionally oriented theory of economic development for the advanced economies of the nonsocialist world. And we need also to fit in the underdeveloped countries. Here clearly we have to be *political* economists, and not just economists in the neoclassical sense. We are currently witnessing powerful political forces at work aimed at improving the terms of trade of the third world with the advanced countries. What will determine the eventual outcome? Mention of the third world raises a host of other issues, political as well as economic. These include the seemingly inexorable advance of socialism in many of these countries;[22] the effect of autocratic forms of government on the pace of economic growth, the allocation of resources, and the distribution of income; and the ability of these countries to deal with the population growth resulting from high birth rates and declining death rates.

And finally, to repeat, there is for economists the basic question to which not only Marx and his followers but also Schumpeter addressed themselves: What is the future of capitalism in the advanced economies, given the growing size and bureaucratization of business firms, the increasing strength of organized pressure groups, and the momentum from the increasing government intervention that has already occurred? It seems to me that capitalism as we know it in this country or even in Western Europe has little future in the third world. What is its future in the advanced economies?

## IV

And so, on this somber note, I end. I have scolded economists for what I think are the sins that too many of them commit, and I have tried to point the way to at least partial redemption. This road to salvation will not be an easy one for those who have been seduced by the siren of mathematical elegance or those who all too often seek to test unrealistic models without much regard for the quality or relevance of the data they feed into their equations. But let us all continue to worship at the altar of science. I ask only that our credo be: "relevance with as much rigor as possible," and not "rigor regardless of relevance." And let us not be afraid to ask—and to try to answer—the really big questions.

[22] Which leads at least this observer to wonder how compatible are democracy and capitalism in an underdeveloped country whose aspirations are rising much faster than its means to satisfy them.

# Uncertainty, Permanent Demand, and Investment Behavior

*By* ELEANOR M. BIRCH AND CALVIN D. SIEBERT*

All investment theories must confront two interrelated questions: how the firm decides upon its optimal or desired capital stock; and how the capital stock is adjusted whenever it differs from the optimal or desired level. Most of the current investment studies assume some static or dynamic certainty model which yields an optimal or desired capital stock.[1] In the real world, it is observed that changes in capital stock are more hesitant, more sluggish than changes in this optimal capital stock would suggest. These studies explain this discrepancy in terms of the adjustment process. Entrepreneurs cannot change capital stock as quickly as they wish because of technologically induced lags, financial constraints, specific costs of adjustment, etc.[2] Such approaches have led to distributed lag formulations.

Because of the durable nature of physical assets and the fact that their accumulation and decumulation involve time and require cost outlays, it is axiomatic that the firm's investment in physical assets depends on the future value of economic variables. However, the future is unknown and any views the entrepreneur has on the future must be uncertain. Unfortunately, the implications of such uncertainty have not been explicitly incorporated into studies of investment behavior.

One purpose of this paper is to incorporate the impact of uncertainty on the firm's investment behavior. When uncertainty is given a realistic weight, it affects the firm's equilibrium conditions and makes it more hesitant, more sluggish with respect to changes in its capital stock than it would otherwise be. The more variable expected demand is, the more hesitant the response of optimal capital stock will be.

The incorporation of uncertainty has additional implications for statistical models that purport to explain or predict investment. If a firm operates within a framework of uncertainty, it appropriately views its demand as consisting of permanent and transitory components, and the transitory portion may be impossible to forecast. Especially in its investment decisions, which are of a long-run nature, the firm may plausibly regard the transitory part of demand as a random error and thus focus on the stable, predictable part, its anticipated permanent demand. But if this is so, then investment estimating equations that use actual demand, actual sales, actual prices, etc., as independent variables are subject to the biases inherent in errors-in-variables formulations.[3] The nature of these biases should help to explain the ob-

[2] For technologically induced lags, see Eisner (1960); for financial constraints, see John Meyer and Edwin Kuh, and James Duesenberry; and for costs of adjustment, see Eisner and Strotz, Arthur Treadway, Hyman Joseph, and Robert Lucas.

[3] The classical discussion of the errors-in-variables problem is in Maurice Kendall and Alan Stuart. For further developments, see Dennis Lindley. For specific examples of the errors-in-variables model applied to economic problems, see Milton Friedman; Gregory Chow, especially Appendix I, pp. 94–98; Tony Lancaster; and Merton Miller and Franco Modigliani.

served underestimation of the elasticity of capital stock with respect to output in distributed lag accelerator regressions.

That firms might, in fact, behave this way was suggested by Eisner (1967), who pointed out the relevance for investment studies of Friedman's permanent income hypothesis and suggested some of the implications of the errors-in-variables formulation for empirical investment studies. Our paper builds on Eisner's suggestions and makes permanent demand the relevant concept for entrepreneurial decisions on investment.

The above topics are approached in the following framework. In the first section the implications for investment behavior of the introduction of costs-of-adjustment and uncertainty are developed. In Section II the problem of changing expectations in an uncertain context is discussed. This leads to the errors-in-variables model as the appropriate statistical approach to the estimation of investment functions. In Section III the statistical model is applied to the accelerator model of investment behavior. The exploratory empirical application confirms the implications of the permanent demand investment model, viz., the estimate of elasticity of capital stock with respect to sales increases significantly; and the length of the estimated average lag decreases when the errors-in-variables estimating approach is employed.

## I. Costs of Adjustment, Uncertainty, and Investment Behavior

In a world of certainty with a perfect capital market, exponentially evaporating capital stock, and costless adjustment of capital stock, the optimal investment behavior of the firm is the relatively simple one of holding for each instant of time that stock of capital for which the marginal revenue product of capital equals the cost of capital.[4] This would imply that if capital stock were pictured as a function of time, it would present a jagged appearance, fluctuating with every vagary of demand. If, more realistically, we assume some costs of adjustment, the capital stock series would become smoother. Even an entrepreneur with perfect foresight would not keep his capital stock perfectly adjusted to optimal output in each period. He would hesitate to increase capital stock even when demand increased, unless the increase were sustained over a long enough period to justify the cost of increasing, then decreasing, capital stock.

This inertia or rigidity in capital stock is reinforced when uncertainty is introduced into the problem.[5] In reality, the entrepreneur does not know the level of demand in any future time period; he must estimate it. When an entrepreneur plans his investment expenditures, he is choosing future levels of capital stock, which depend on his expectations about future demand. But these expectations are formed under uncertainty; thus, there is an additional opportunity cost associated with the investment decision, viz., the cost of making an incorrect estimate about future demand. Moreover, since the entrepreneur's perception of demand is hazy under uncertainty, a shift in demand due, say, to a change in consumer tastes, is difficult to distinguish from a random fluctuation. Thus, the entrepreneur's response to such a change is hesitant, and especially so with respect to the investment decision, which depends on longer range (i.e., more uncertain) rather than shorter range forecasts.

In such an environment, the investment decision can be viewed as follows. The entrepreneur makes a long-range forecast of demand (for example, one year) which implies a series of short-range forecasts (for example, monthly during the year).

[4] See Kenneth Arrow for a demonstration of these results.

[5] For further development of this notion, see the paper by Guy Stevens. Also, the issue is treated in a longer version of this paper available from the authors on request.

The entrepreneur decides on his optimal capital stock on the basis of the long-range forecast, and the difference between this and his current capital stock determines his investment. He then proceeds to produce from month to month on the basis of his short-run equilibrium conditions and his original long-range forecast, as long as the forecast is validated by events. The entrepreneur's problem then becomes how to decide when a forecast has become invalid. One way to describe how the entrepreneur behaves under these conditions is to picture him as adopting a hypothesis-testing approach. That is, the entrepreneur continues to accept the null hypothesis that demand has not permanently changed unless events convince him otherwise.

If the entrepreneur accepts the null hypothesis, he continues to leave his capital stock unchanged; but if the entrepreneur rejects it, he makes a new long-range forecast of permanent demand, chooses a new optimal capital stock on the basis of this forecast, and invests (disinvests) accordingly. This behavior on the part of the firm suggests that minor fluctuations in demand (those consistent with the long-range forecast) are met by moving along the short-run cost curve while significant changes in demand cause a long-run response. That is to say, the entrepreneur balances the opportunity loss he risks by making a wrong decision on capital stock against the opportunity loss he makes by operating on his higher short-run cost curve rather than on his lower long-run curve. As long as the former exceeds the latter, the entrepreneur leaves his capital stock unchanged. When the two reverse positions, so that the latter exceeds the former, the entrepreneur will invest (disinvest) so as to change capital stock.

Thus the entrepreneur in the face of uncertainty in conjunction with positive costs-of-adjustment will be quite sluggish in making changes in capital stock. A decision to change capital stock will be made only after the entrepreneur decides demand has changed permanently. Such a decision may take several periods of observation. Even after a decision has been made that permanent demand has changed, costs-of-adjustment may deter an immediate movement to the entrepreneur's optimal capital stock.

## II. Expectations, Permanent Demand, and Errors in Variables

Looking at the decision problem for the entrepreneur faced with uncertainty and high costs of adjustment as one in which the entrepreneur makes a new long-run forecast when he rejects the hypothesis that permanent demand has not changed, one is faced with the question of how to capture the changes in the entrepreneur's expectations for purposes of estimation. One approach to this problem is the adaptive expectations formula of Phillip Cagan and Marc Nerlove which has become quite popular. As Edwin Mills shows, however, such an autoregressive model implies biased expectations. Mills demonstrates that any predictive information in an autoregressive scheme will be better utilized if it is built into the vector of explanatory variables. Thus a regression equation using the expectational variable as the dependent variable and any other explanatory variables we think relevant as the independent variables (including, if desired, past values of the expectational variable itself) should provide a better estimate. If, for example, we assume a fixed-price model, then anticipated permanent demand for some future period consists of anticipated permanent sales. If we make the assumption that on the average entrepreneurs guess correctly about their future sales, then we can regress actual sales on a set of explanatory variables, thus obtaining regression coefficients with which to form a predictive equation for anticipated permanent sales. If some such scheme is not followed, but instead actual

sales are used as an independent variable in an investment equation instead of anticipated permanent sales, then the statistical problem of errors-in-variables is likely to be encountered.[6]

The relevance of the errors-in-variables analysis for investment studies is obvious. Take, for example, the accelerator model of investment. In its most general form it focuses on a generally accepted economic doctrine, viz., that the demand for capital is a derived demand.[7] But it is not necessary to link investment with historical changes in sales to preserve this truth. It is really anticipated long-run optimal sales, not historical output, that is functionally related to optimal capital stock. Investment then depends on changes in anticipated long-run optimal sales, which do not necessarily occur *pari passu* with actual sales changes especially where imperfect knowledge is the rule. Optimal capital stock will tend to be more sluggish under uncertainty than actual output. This suggests that investment depends on changes in permanent demand (or, in a fixed-price model, permanent sales) rather than in actual demand (sales) under the assumption of a fixed system of cost curves.

Now if this view of investment is valid, it suggests that traditional formulations of the investment equation based on the accelerator theory lead to inconsistent estimates of the parameters of that function, in just the same way that consumption functions based on measured income yield inconsistent estimates of the marginal propensity to consume. Investment literature abounds with accelerator-type regressions where the elasticity of capital stock with respect to output is considerably lower than the postulated figure of unity. Many possible explanations are proffered: (a) the firm was not operating at full capacity so the full accelerator was not operative; (b) other factors, for example, the firm's liquidity, must also be taken into account; and (c) the firm is never in equilibrium because of various costs of adjustment. Reason (c) led to the various distributed lag formulations. Now many or even all of these explanations could be true in some particular case, but the existence of the classic errors-in-variables problem may well explain part of the discrepancy.

Consider an accelerator-type investment equation in which investment in year t is regarded as a linear function of the change in sales in the previous year as well as of other explanatory variables such as a capacity indicator, profits, etc., the latter variables added to account for times when the strong accelerator is inoperative:

$$I_t = b_0 + b_1(S_t - S_{t-1}) + \sum_{i=2}^{m} b_i X_{i,t-1} + v_t \tag{1}$$

To the extent that the actual sales change in (1) is a proxy for the expected sales change, the coefficient $b_1$ will be biased downward. The "true" relation would be:

$$I_t = \beta_0 + \beta_1(S_t^* - S_{t-1}^*) + \sum_{i=2}^{m} \beta_i X_{i,t-1} + u_t \tag{2}$$

where $E(u_t) = E(u_{t-r}) = 0$, for all $r$;

$$cov\,(u_{t-i}, u_{t-j}) = \begin{cases} \sigma_u^2, & i = j \\ 0 & \text{elsewhere} \end{cases}$$

**But**

$$\begin{aligned} S_t &= S_t^* + e_t \\ S_{t-1} &= S_{t-1}^* + e_{t-1} \end{aligned} \tag{3}$$

[6] The earliest econometric efforts were usually errors-in-variables models, but for the past generation, errors-in-equation models have superseded them. Friedman's consumption function based on permanent income rejuvenated the errors-in-variables approach.

[7] The accelerator model is employed since the statistical approach developed here can be applied in a more straightforward manner than in other models of investment behavior. Also, Eisner (1967) suggested the errors-in-variables approach for the accelerator model.

where $E(e_t)=E(e_{t-r})=0$, for all $r$;

$$cov\,(e_{t-i}, e_{t-j}) = \begin{cases}\sigma_e^2 & i=j\\ 0 & \text{elsewhere}\end{cases}$$

Therefore, $S_t^*-S_{t-1}^*=S_t-S_{t-1}-(e_t-e_{t-1})$ where $E(e_t-e_{t-1})=0$ and $var\ (e_t-e_{t-1})=2\sigma_e^2$. If (1) is estimated when (2) is the true model, then (1) becomes indistinguishable from:

$$(4)\quad I_t = \beta_0 + \beta_1(S_t - S_{t-1}) + \sum_{i=2}^{m} \beta_i X_{i,t-1} + u_t - \beta_1(e_t - e_{t-1})$$

or

$$I_t = \beta_0 + \beta_1(S_t - S_{t-1}) + \sum_{i=2}^{m} \beta_i X_{i,t-1} + v_t$$

where $v_t=u_t-\beta_1(e_t-e_{t-1})$. Then the covariance between the error term and the independent variable (under the usual assumption that $u$ and $e$ are independent) is

$$(5)\quad E\{v_t[(S_t - S_{t-1}) - E(S_t - S_{t-1})]\} = -2\beta_1\sigma_e^2$$

which will be zero only when there is no measurement error in the independent variable or in the trivial case where $\beta_1=0$. In general, this covariance will be nonzero and therefore (1) will be subject to the equivalent of the familiar simultaneous equations bias. In the limit, for large samples, the coefficient of actual sales change $b_1$ will be biased downward as an estimator of $\beta_1$. The other regression coefficients are also affected, being biased upward (downward) if their variable is positively (negatively) related to permanent sales changes.[8]

From the above discussion, it would seem that the model dealt with here is actually a system of simultaneous equations:

$$(6a)\quad I_t = \beta_0 + \beta_1(S_t^* - S_{t-1}^*) + \sum_{i=2}^{m} \beta_i X_{i,t-1} + u_t$$

$$(6b)\quad S_t = S_t^* + e_t$$
$$S_{t-1} = S_{t-1}^* + e_{t-1}$$

$$(6c)\quad S_t^* = \gamma_1 + \sum_{i=2}^{m} \gamma_i X_{i,t-1} + \omega_t$$
$$S_{t-1}^* = \gamma_1 + \sum_{i=2}^{m} \gamma_i X_{i,t-2} + \omega_{t-1}$$

where $I_t$= net investment in year t; $S_t^*$= true but unobservable permanent sales in year t; $S_t$= actual sales in year t; $X_i$, $i=2, \ldots, m$ stand for all other relevant variables, some $\beta_i$ and $\gamma_i$ may be zero; and with the error terms assumed independent of each other and with means zero and constant variances of $\sigma_u^2$, $\sigma_e^2$, and $\sigma_\omega^2$, respectively. Equations (6) thus constitute a system in which both $I$ and $S$ are treated as endogenous; only the $X_i$ are truly exogenous variables. When (6a) is estimated with actual sales used in place of permanent ones, actual sales are erroneously treated as exogenous variables, leading to the familiar simultaneous equations bias.

One way to reduce the bias in $\beta_1$ is to follow the instrumental variable approach suggested by equations (6). First the endogenous variable $S_t$ can be regressed on all the instrumental variables $X_i$ in (6c). From these estimates a new variable, $\hat{S}_t$, is formed, defined as:

$$(7)\quad \hat{S}_t = g_1 + \sum_{i=2}^{m} g_i X_{i,t-1}$$

This variable provides an estimate of $S_t^*$ from which much of the measurement error $e_t$ will have been removed. If $\hat{S}_t$ is then used in the second stage as the sales variable in place of $S_t^*$, with $\hat{S}_{t-1}$ for $S_{t-1}^*$, the resulting estimates of the $\beta_i$ should be more accurate estimates of the $\beta_i$ in the basic

[8] See Chow, pp. 94–98, for detailed proofs.

structural equation (6a). The task then is to estimate (6a), first using $(S_t - S_{t-1})$ as the main independent variable, then note the difference when it is estimated with $(\hat{S}_t - \hat{S}_{t-1})$ as the main independent variable, in a two-stage procedure. The result should be that the coefficient of the sales-change variable should increase in the second stage.

The two-stage procedure can also shed some light on an old controversy in the investment literature, viz., the role of profits in investment. Jan Tinbergen held that the prospect of future profits induces investment and that current profits are an indicator of future profits. Thus profits enter the investment picture on the demand side; i.e., they directly influence the firm's desire to expand. There is another school of thought about profits, however, associated with Meyer and Kuh and with Duesenberry, among others, which maintains that profits affect the supply of funds that finance investment. This notion depends on the assumption that external capital rationing exists or that firms, for this or whatever reason, prefer to finance their expansion out of retained earnings.

The usual course taken in investment studies is simply to add a profits variable (or several) with unspecified coefficient to the structural equation and let the sample determine its value. The trouble with this approach, however, is that if applied in this simplistic fashion, the resulting estimate of the profits coefficient (in the liquidity, or supply-side sense) will, because of the errors-in-variables problem, inevitably be upward biased and the sales-change coefficient correspondingly downward biased. To the extent that Tinbergen's view is valid, the profits coefficient in the regression equation will reflect substantial informational content about expected earnings (which, in this model, is reflected by $S_t^*$, expected sales) along with the supply effect, if any, of profits per se on investment. This could help to explain some empirical results obtained in many studies with respect to profits. When profits have been included as an explanatory variable along with actual sales changes, their coefficients have usually been positive and sometimes significantly so. But this is consistent with a true value of zero for the profits coefficient (in the liquidity sense) if profits are positively correlated with expected sales, as Tinbergen would maintain. This confounding of profits' supply and demand effects can be reduced by a two-stage procedure and some, at least, of the demand-side content of profits can be salvaged. To the extent that profits contribute anything to equation (6c), their coefficient should be lower when $(\hat{S}_t - \hat{S}_{t-1})$ is used in (6a) than it is when $(S_t - S_{t-1})$ is used. The profits coefficient in (6c) should provide some idea of their demand-side influence, and their coefficient in (6a)—when $(\hat{S}_t - \hat{S}_{t-1})$ is used—should indicate their liquidity or supply-side influence.

Another implication of this approach is that if the method succeeds in estimating anticipated permanent demand, the average lag that can be derived from the estimated investment equations should be shorter when anticipated permanent sales changes are used than when actual sales changes are entered into the regression.

## III. Empirical Results

To test the model developed above, a pilot study of a group of eight large *U.S.* industrial firms was undertaken. These firms were chosen mainly because 1934–63 data were available for them in a particularly convenient form, as a result of earlier studies by Jorgenson and Siebert.[9]

[9] The data sources and measurement methods are the same as those of the Jorgenson and Siebert studies. The firms used in this study were: 1) American Can Co., 2) General Electric Co., 3) General Motors Corp., 4) International Business Machines, 5) R. J. Reynolds Tobacco Co., 6) Standard Oil Co., 7) Swift and Co., and 8) U.S. Steel Corp. Details on data measurement are

These figures were then extended through 1966 except in a few instances where the company's method of accounting had changed and the data would no longer be comparable.

The variables used in the regressions are defined as follows:

$S_{t-1}$ = the firm's sales in year t−1.

$\hat{S}_t$ = the firm's predicted permanent sales for year t estimated on the basis of knowledge through year t−1.

$P_{t-1}$ = the firm's profits before taxes in year t−1.

$S^I_{t-1}$ = the industry's sales in year t−1.

$MVF_{t-1}$ = the market value of the firm at the end of year t−1. This is the sum of the firm's debt and the market value of its equity. Yehuda Grunfeld used this as an indicator of expected future profits.

$I_t$ = the firm's investment in fixed plant and equipment during year t.

$D_t$ = estimated replacement, i.e., "true" depreciation for the firm in year t.[10]

The first-stage set of regressions consisted of four equations estimating permanent sales. These estimates were assumed to be made before the fact, i.e., under conditions of uncertainty. The instrumental variables used were the firm's own sales, its profits, its market value, and the sales of its industry. In the first equation these independent variables were expressed as three-year averages in order to remove transitory effects. For the firm's own sales, this choice seems reasonable, but for the other variables it is possible that changes in their levels or even their growth rates might be more meaningful. For example, a firm might be more inclined to believe its sales would increase if its profits were increasing rather than merely high, and it might be more influenced by a high growth rate of its industry's sales rather than by its current high level. Accordingly, the second equation used these instrumental variables expressed as a change in their levels from year t−2 to year t−1 and the third used them expressed as growth rates or percentage changes from year t−2 to t−1. Thus, the first three estimating equations were as follows:

$$(8)\quad (\hat{S}_t) = g_0 + g_1[1/3(S_{t-1}+S_{t-2}+S_{t-3})] + g_2[1/3(P_{t-1}+P_{t-2}+P_{t-3})] + g_3[1/3(S^I_{t-1}+S^I_{t-2}+S^I_{t-3})] + g_4 MVF_{t-1}$$

$$(9)\quad (\hat{S}_t) = g_0 + g_1[1/3(S_{t-1}+S_{t-2}+S_{t-3})] + g_2(S_{t-1}-S_{t-2}) + g_3(P_{t-1}-P_{t-2}) + g_4(S^I_{t-1}-S^I_{t-2}) + g_5(MVF_{t-1}-MVF_{t-2})$$

$$(10)\quad (\hat{S}_t) = g_0 + g_1[1/3(S_{t-1}+S_{t-2}+S_{t-3})] + g_2\left(\frac{S_{t-1}-S_{t-2}}{S_{t-2}}\right) + g_3\left(\frac{P_{t-1}-P_{t-2}}{P_{t-2}}\right) + g_4\left(\frac{S^I_{t-1}-S^I_{t-2}}{S^I_{t-2}}\right) + g_5\left(\frac{MVF_{t-1}-MVF_{t-2}}{MVF_{t-2}}\right)$$

The results of these first three equations were then used to decide upon a fourth and

contained in a longer version of this paper available from the authors on request.

[10] Given investment at constant prices and two benchmark capital stock figures, all other capital stock and replacement data were computed from an explicit model for replacement, assuming that replacement was a constant fraction of capital stock at the start of each year. This yielded a difference equation that could be solved for an estimate of the "true" depreciation rate. This in turn was used to compute a "true" depreciation series.

final version. The fourth equation used as independent variables those that were found to be significant in the first three formulations. Thus, permanent sales in year t were estimated as a function of the firm's average sales in the preceding three years, a variable whose coefficient differed significantly from zero in all three earlier versions; the firm's market value at the beginning of year t, significant in the first equation; the change in the firm's profit level during the preceding year, significant in the second equation; the change in the firm's market value during the preceding year, significant in the second equation; the growth rate of the industry's sales during the preceding year, significant in the third equation; and lastly, the firm's profits in the preceding year. The profits variable was added in order to separate the demand-side, informational contribution of the profits variable from the liquidity or supply-side contribution it might make to the subsequent second-stage investment equations. Thus, the fourth equation was of the form:

$$(11)\quad (\hat{S}_t) = g_0 + g_1[1/3(S_{t-1} + S_{t-2} + S_{t-3})] + g_2 MVF_{t-1} + g_3(P_{t-1} - P_{t-2}) + g_4(MVF_{t-1} - MVF_{t-2}) + g_5\left(\frac{S^I_{t-1} - S^I_{t-2}}{S^I_{t-2}}\right) + g_6 P_{t-1}$$

The regression program used for the above four equations had a stepwise feature which permitted each variable to enter the regression singly, in order of importance. For example, if one independent variable was already in the equation, the next variable to be added to the equation would be the one with the highest $F$-level for entrance. Because of multicollinearity among the explanatory variables, the addition of a third or fourth variable often added virtually nothing in the way of fresh explanation; its main effect was to render insignificant the coefficients of variables previously added. To rule out these overly collinear effects, the rule adopted was to accept as final the equation where any omitted variable, if it were to enter, would render insignificant the coefficient of any variable in the equation, including its own (at a significance level of 95 percent).

The results for all four equations predicting permanent sales are shown in Table 1. The independent variables shown in the table are considerably fewer than those shown above because many of those originally considered turned out to be insignificant; only those whose coefficients were significantly different from zero at the 95 percent level are shown in Table 1.

The firm's own sales average was, as expected, most helpful in predicting its permanent sales. Industry sales were less important.[11] But profits entered significantly into two of the equations as did the market value of the firm variable. These results tend to confirm Grunfeld's belief that this variable has expectational content.

Since the fourth equation was the most general in that it allowed the instrumental variables to enter in any form, and since it estimated sales with slightly greater accuracy ($R^2 = .98$) than the other three ($R^2 = .97$), it was selected as the "best" predictor of permanent sales. The fourth equation was then used to generate a series of permanent sales which could be used in the second-stage problem, the investment estimation equation.

The simplest possible version of an accelerator-type investment equation would be one that made gross investment in year

[11] This would appear to contrast with Eisner's (1967, pp. 368, 374) results in which he hypothesizes that firms view variations in their industry's sales as a better predictor of their future prospects than their own past sales experience. However, the firms included in this study are the largest in their industries, so they may dominate the industry influence.

TABLE 1—RESULTS OF FOUR REGRESSIONS PREDICTING PERMANENT SALES IN YEAR t AS A FUNCTION OF SPECIFIED VARIABLES

| | | Regression Coefficients and Standard Errors | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Equation | $R^2$ | Constant Term | $\frac{1}{3}(S_{t-1}+S_{t-2}+S_{t-3})$ | $MVF_t$ | $P_{t-1}-P_{t-2}$ | $MVF_t-MVF_{t-1}$ | $\frac{S^I_{t-1}-S^I_{t-2}}{S^I_{t-2}}$ | $P_{t-1}$ |
| (8) | .97 | 14.00 | 1.019 | .0682 | | | | |
| | | (62.23) | (.0305) | (.0183) | | | | |
| (9) | .97 | 11.55 | 1.089 | | .6257 | .1699 | | |
| | | (59.38) | (.0145) | | (.2048) | (.0377) | | |
| (10) | .97 | −86.00 | 1.124 | | | | 864.4 | |
| | | (69.49) | (.0145) | | | | (282.4) | |
| (11) | .98 | 96.09 | .9113 | .0464 | | | | .7340 |
| | | (64.75) | (.0421) | (.0189) | | | | (.2038) |

t a function of the firm's replacement needs, i.e., its true depreciation, and its current year sales change:

$$I_t = \beta_0 + \beta_1(D_t) + \beta_2(S_t - S_{t-1}) + u_t \tag{12}$$

This is perhaps overly simplified but it does serve to focus attention on the sales-change variable which is of primary interest here. Accordingly, equation (12) was estimated in two forms: first, with actual sales used for $S_t-S_{t-1}$ and then with permanent sales, $\hat{S}_t-\hat{S}_{t-1}$, yielded by equation (11). The results are presented in Table 2.

When the permanent rather than the actual sales change was used as the independent variable, the regression equation explained 73 rather than 47 percent of the variation in investment. The coefficient of the sales change variable rose from .0569 when actual sales were used to .4052 when permanent sales were used; the increase was statistically significant at the 99.5 percent confidence level.

TABLE 2—RESULTS OF THREE PAIRS OF REGRESSIONS ESTIMATING INVESTMENT ACCORDING TO EQUATIONS (12), (17), AND (18), USING ACTUAL SALES AND PREDICTED PERMANENT SALES

| | | Regression Coefficients and Standard Errors | | | | | |
|---|---|---|---|---|---|---|---|
| Equation | $R^2$ | Constant Term | $D_t$ | $S_t-S_{t-1}$ | $I_{t-1}$ | $S_{t-1}-S_{t-2}$ | $P_{t-1}$ |
| (12a) Using actual sales | .47 | 129.3 | .6024 | .0569 | | | |
| | | (21.48) | (.0488) | (.0274) | | | |
| (12b) Using predicted permanent sales | .73 | 68.80 | .5585 | .4052 | | | |
| | | (15.85) | (.0339) | (.0281) | | | |
| (17a) Using actual sales | .93 | 6.865 | .0527 | .0462 | .8909 | .0847 | |
| | | (8.751) | (.0252) | (.0106) | (.0307) | (.0109) | |
| (17b) Using predicted permanent sales | .93 | 7.873 | .1002 | .1629 | .8430 | −.0392 | |
| | | (8.504) | (.0259) | (.0181) | (.0370) | (.0198) | |
| (18a) Using actual sales | .94 | 5.941 | .0241 | .0414 | .6868 | .0467 | .1462 |
| | | (8.072) | (.0237) | (.0098) | (.0440) | (.0119) | (.0242) |
| (18b) Using predicted permanent sales | .94 | 7.320 | .0469 | .0879 | .7223 | −.0540 | .1313 |
| | | (8.159) | (.0277) | (.0245) | (.0452) | (.0288) | (.0304) |

It was suggested above that equation (12) is a rather simplified formulation. Because of costs-of-adjustment it is not optimal for a firm to adjust its capital stock quickly. Such partial adjustment can lead to a flexible accelerator model of investment in which not only the current year's sales changes, but also the preceding years' changes enter the regression.[12] This leads to a distributed lag formulation of the investment equation. Some authors, notably Eisner (1960), have included as many as seven sales-change variables in an investment equation of this type. It is possible to suggest the same process, while economizing on variables, by using some version of a Koyck-type distributed lag.[13] This can be done by assuming that beyond some time period in the past, the influence of prior periods decreases geometrically. For example, net investment in year t, $Q_t$, can be considered to be a linear function of all past sales changes (either actual or permanent). Thus:

$$(13) \quad Q_t = a_0 + a_1\Delta S_t + a_2\Delta S_{t-1} + a_3\Delta S_{t-2} + a_4\Delta S_{t-3} + \ldots$$

Gross investment in year t, $I_t$, would be net investment $Q_t$ plus replacement investment $R_t$, so:

$$(14) \quad I_t = R_t + a_0 + a_1\Delta S_t + a_2\Delta S_{t-1} + a_3\Delta S_{t-2} + a_4\Delta S_{t-3} + \ldots$$

The decreasing geometric series can be introduced at any point. If one wishes, one can estimate any finite number of the $a_i$, $i=0, \ldots, \infty$, assuming that the remaining $a_{i+j}$, $j=1, \ldots, \infty$, are related to $a_i$ as follows:

$$(15) \quad a_{i+j} = h^j a_i, \qquad 0 < h < 1$$

[12] See Eisner and Strotz and Lucas for a demonstration that introducing costs-of-adjustment in the investment function can lead to a flexible accelerator-type investment model.

[13] A Koyck-type distributed lag is sufficient for our purposes since we are not attempting to estimate the best form of the lag function.

For example, if one estimates only the first two sales-change coefficients and permits the geometric decrease to begin beyond that point, one can derive:

$$(16) \quad I_t = (1 - h)a_0 + (R_t - hR_{t-1}) + hI_{t-1} + a_1\Delta S_t + (a_2 - ha_1)\Delta S_{t-1}$$

Because of the presence of $R_t$ and $R_{t-1}$ in this equation, the multicollinearity problem would be severe if it were estimated in this form. Since the replacement (true depreciation) series used here varied very little from one year to the next, $(R_t - hR_{t-1})$ was assumed to be approximately equal to $(1-h)R_t$, so equation (16) above became the following equation to be estimated here:

$$(17) \quad I_t = \beta_0 + \beta_1(D_t) + \beta_2(I_{t-1}) + \beta_3(S_t - S_{t-1}) + \beta_4(S_{t-1} - S_{t-2}) + U_t$$

where $\beta^0 = (1-h)a_0$, $\beta_1 \sim (1-h)$, $\beta_2 = h$, $\beta_3 = a_1$, and $\beta_4 = a_2 - ha_1$.

Equation (17) was then estimated in two forms: first, with actual sales used for $S_t - S_{t-1}$ and $S_{t-1} - S_{t-2}$; and then with permanent sales $\hat{S}_t - \hat{S}_{t-1}$ and $\hat{S}_{t-1} - \hat{S}_{t-2}$, yielded by equation (11). The results are presented in Table 2.

Based on the earlier discussion, we should expect that equation (17b) would explain investment at least as well as—hopefully, better than—equation (17a), and that the coefficient of $S_t - S_{t-1}$ would be larger in (17b) than in (17a). Also, owing to the derivation of equation (17), $\hat{\beta}_4$, the coefficient of $(S_{t-1} - S_{t-2})$, can be used together with $\hat{\beta}_2$ and $\hat{\beta}_3$ to estimate the original distribution lag coefficients $a_1$, $a_2$, and all remaining ones if desired. If this were done, then we should expect that the distributed lag estimated from (17a), the actual sales equation, would be longer than the one estimated from (17b), the permanent sales equation. In other words, the

two-stage procedure should serve to disentangle the purely expectational lag from the costs-of-adjustment one. To the extent that the expectational lag has already been subsumed under the permanent sales variable, there should remain only the costs-of-adjustment lag. So the estimated value of $a_3$ in equation (13) should decrease when permanent sales are substituted for actual sales in the estimation of equation (17). This, together with an increase in $a_1$, would imply the lag has been foreshortened.

As can be seen from Table 2, equation (17b) was at least as good as equation (17a) in explaining investment, since 93 percent of the variation in investment was explained by each. (Actually, equation (17b) was very slightly better with $R^2 = .930$ as compared with $R^2 = .927$ for equation (17a).) The change in the coefficient of $S_t - S_{t-1}$ was also in the predicted direction, increasing substantially when permanent sales were used. The increase was statistically significant at the 99.5 percent confidence level. The estimates of $a_1$, $a_2$, and $a_3$ for the actual sales version were .0462, .1259, and .1122, respectively. For the permanent sales version, they were .1629, .0981, and .0847, so the distributed lag has indeed been shortened by the two-stage procedure.

The investment equations considered thus far have made no allowance for liquidity or supply-side variables. As mentioned earlier, Duesenberry and Meyer and Kuh, among others, have stressed the importance to investment of a high level of profits. The investment equation previously considered could be altered to include a profits variable as follows:

$$
\begin{aligned}
(18)\quad I_t = {} & \beta_0 + \beta_1(D_t) + \beta_2(I_{t-1}) + \beta_3(P_{t-1}) \\
& + \beta_4(S_t - S_{t-1}) + \beta_5(S_{t-1} - S_{t-2}) \\
& + U_t
\end{aligned}
$$

Since equation (18) contained the profits variable[14] that was included in equation (11), the estimate of permanent sales, estimating equation (18) in two ways with actual sales and with permanent sales should serve to sort out the demand-side and supply-side effects of the previous year's profits on investment. Accordingly, this equation was estimated with the results shown in Table 2. The increase in the coefficient of $S_t - S_{t-1}$ when permanent sales were substituted for actual ones was statistically significant at the 95 percent confidence level. The change in the estimated lag structure here was also as predicted. Estimates of $a_1$, $a_2$, and $a_3$ were .0414, .0751, and .0516 for the actual sales equation; they were .0879, .0095, and .0069, respectively, for the permanent sales equation.[15]

The main reason for estimating equation (18) was to observe the behavior of $\hat{\beta}_3$, the coefficient of the profits variable. If

[14] There is some question as to what measure of profits should be included in the second-stage or investment equation regression. Kuh, p. 63, suggested profits after taxes plus depreciation less dividends paid as an appropriate measure for the supply of funds impact on investment. In the results reported here, however, the same profits variable was employed in both stages of estimation—in estimating permanent sales and in the second-stage investment equation.

[15] To rule out the possibility that these results might be spurious owing to the presence of heteroskedasticity, the investment equations were also estimated in ratio form, with each equation divided through by capital stock, an indicator of firm size. The results were not materially changed. The Durbin-Watson statistic was used to check independence; for what it is worth, this gave favorable results (i.e., no evidence of serial correlation) for all equations except (12a) and (12b), which are no doubt misspecified. But the Durbin-Watson test is not strictly applicable to the case where lagged variables are used and it is biased toward a favorable result in that event. Nevertheless, there is reason to believe that autocorrelation in the residuals is not a major problem. The focus of this study was not on the estimation of coefficients for their own sake, but on ascertaining whether the use of different sales variables gives rise to differences in regression coefficients. For each pair of equations compared, any irregularity such as autocorrelation would be expected to occur in both versions. Thus, differences between them which were of primary interest here should not be appreciably affected in any event.

profits have any demand-side influence, i.e., if they affect the estimate of permanent sales, then the coefficient of the profits variable should be lower in equation (18b) than in equation (18a). This is because the demand-side influence of this variable should already be reflected in the permanent sales variable used in (18b) while it is not so reflected in the actual sales variable used in (18a). How much lower the coefficient would become is a moot question, since it depends on the relative strengths of the demand-side and supply-side influences of this variable. As can be seen from Table 2, the profits coefficient did decrease in equation (18b) as predicted but the decrease was not very large. In fact, there is about a one-third chance that the decrease was not statistically significant. From this test, then, it would appear that the profits variable could have both a demand-side and a supply-side influence on investment. Further tests with larger samples should permit better estimates of their magnitudes.

## IV. Concluding Remarks

The results of the empirical analysis were consistent with our expectations: the estimated elasticity of capital stock with respect to sales increased, and the estimated average lag decreased when the instrumental errors-in-variables approach was employed. The empirical results also lend support to the hypothesis that an entrepreneur faced with uncertainty will tend to adjust only when he considers changes to be permanent. Our results suggest that further work with an instrumental errors-in-variables approach for investment behavior may prove fruitful, especially in disentangling supply-side from demand-side effects of profits. Our results are also consistent with those of Eisner (1967). He found that sales expectations of firms have some role in explaining investment over and above that provided by actual current and lagged sales changes.

In addition, the results have implications beyond the confines of investment behavior. Most economic acts are based upon expectations formed about an uncertain future. Under such conditions, economic agents' behavior will tend to depend on anticipated permanent values of relevant decision variables. If that is the case, the two-stage instrumental errors-in-variables approach employed in this paper may be a more appropriate estimation procedure than the conventionally used errors-in-equation model.

# Rational Expectations in a Disequilibrium Model of the Term Structure

By MICHAEL E. ECHOLS AND JAN WALTER ELLIOTT*

Many of the recent tests of theories on the term structure of interest rates have been based on variants of an expectations model first developed by David Meiselman. Studies by Reuben Kessel and James Van Horne use variants of Meiselman's model in the attempt to empirically test various aspects of term structure theory. The models of Meiselman, Kessel, and Van Horne share the presumption that interest rate expectations are autoregressively related to prior and present components of the term structure according to an error-learning hypothesis.[1] Other work, most notably by Richard Roll and Thomas Sargent (1973), has examined the related proposition that interest rate expectations are a martingale or a sub-martingale. Sargent's results do not support the representation of interest rate expectations as a martingale or sub-martingale, while Roll's somewhat positive results are confined to the very short expectations embodied in the Treasury Bill market.

The formulation of the term structure as an essentially autoregressive model places the resulting theory in isolation from other components of the economic system and leaves several important questions unresolved. The role played by current economic variables in the formation of the type of interest rate expectations postulated by Irving Fisher, John Hicks, Friedrich Lutz, and others, remains unclear. Neither classical nor Keynesian concepts of interest rate determination are directly incorporated in the investor's expectational framework. Nonetheless, empirical evidence such as that presented by Sargent (1968), Martin Feldstein and Otto Eckstein, Thomas Yohe and Dennis Karnosky has shown that economic variables significantly affect the level of interest rates. Finally, the decreased ability of the error-learning model to explain the level of forward rates as longer time horizons are considered indicates the desirability of an expanded theory of investor expectations.[2]

In this paper, we develop a model of the term structure based on the premise that expectations of future spot rates are primarily determined by current and past economic behavior. The model is based upon a four-sector loanable funds representation of equilibrium interest rates. The solved structure of this model is used as the basis for the estimation of expected rates according to the rational expecta-

[1] Meiselman's original structure is:

$$_{t+n}E_t - {}_{t+n}E_{t-1} = \beta(R_{t\cdot 1} - {}_tE_{t-1}) + \alpha$$

where $_{t+n}E_t$ is the expectation of the one-period spot rate $n$ periods in the future held by investors at time t; $R_{t\cdot 1}$ is the one-period spot rate occurring at time t; and $\alpha$, $\beta$ are constants.

[2] Meiselman's results for the error-learning model are:

| Year of Forward Rate | Correlation Coefficient |
|---|---|
| $n=1$ | .952 |
| 2 | .867 |
| 3 | .768 |
| 4 | .682 |
| 5 | .642 |
| 6 | .625 |
| 7 | .631 |
| 8 | .590 |

The error-learning model does an increasingly poor job of explaining longer forward rates.

tions concept proposed by John Muth. Our model of rationally based expected rates is incorporated into a disequilibrium framework that enables empirical testing of the role of expectations, liquidity factors, and institutional supply and demand factors in explaining fluctuations in forward rates over time.

In the pure expectations theory of the term structure discussed by Lutz and Meiselman, speculation is active across all maturity regions. The existence of risk-neutral investors drives the structure of forward rates implicit in the yield curve into close alignment with expected future spot rates. If forward rates rise above market expectations of future spot rates, demand builds for the appropriate forward contracts, bond prices rise for the maturities involved, and market equilibrium in which forward rates align with expected future spot rates is restored. Hicks and others have proposed modifications of this structure to accommodate a risk premium for longer maturity securities. In this view, observed forward rates consist of a risk premium as well as expectations of future spot rates. John Culbertson has argued that the existence of institutional barriers reduces the influence of speculative activity by inhibiting the leveling of forward rates with expectations. He proposes that customary investment maturity regions exist for a number of institutional investors, such that their liquidity requirements and cash flow position can affect some regions of the yield curve disproportionately more than other regions.

Empirical tests of the existence of risk premiums have been made by Meiselman, Van Horne, J. Huston McCulloch, and ourselves (1975a) using variants on the error-learning model described in footnote 1. Although Meiselman's original results are not sufficient to support his conclusions, for reasons given by Reuben Kessel, the conclusion of the other studies is that the existence of risk premiums appears to have positive empirical support. Direct empirical tests of the market segmentation ideas of Culbertson have been limited. Franco Modigliani and Richard Sutch (1966, 1967) have developed and tested a variant of Culbertson's model that emphasizes the impact of bond market supply upon market equilibrium between long and short maturity bonds. However, the results of their tests are quite mixed. In addition, Douglas Fisher has reported evidence of market segmentation for British securities, while Jacob Michaelson has conducted tests on holding period yields using Treasury data and has reported results unfavorable to a market segmentation view. Previous work undertaken by the present authors (see Elliott and Echols 1976) finds evidence of frequent market segmentation in longer maturity regions for U.S. Treasury bonds.

## I. A Disequilibrium Structure

None of the empirical tests now discussed has proceeded on the assumption that present expectations of future spot rates are primarily governed by aggregate economic behavior. By contrast, this assumption is a central premise of the work reported upon here. We begin with the well-accepted premise that forward market rates of interest contain substantial if not exclusive information on expectations of investors concerning future spot rates of interest. Forward rates are implied by the current term structure of yields according to:

$$(1) \qquad {}_{t+n}r_t \equiv \frac{(1 + R_{n+1,t})^{n+1}}{(1 + R_{n,t})^n} - 1$$

where $R_{n,t}$ is the spot rate of discount on $n$-period money as of time t and ${}_{t+n}r_t$ is the forward market rate of interest at time t on one-period money t$+n$ periods into the future that investors could be assured of by shorting $n$-period contracts and buying an

equal long position in $n+1$ period contracts.

To structure our model of forward rate determination, we employ a market disequilibrium framework.[3] This framework recognizes that at any point in time a given forward rate may not be fully adjusted to its equilibrium value, and that a given forward rate may or may not contain a liquidity premium. The disequilibrium framework is:

$$(2) \quad {}_{t+n}r_t \equiv {}_{t+n}E_t + ({}_{t+n}far_t - {}_{t+n}E_t) + ({}_{t+n}r_t - {}_{t+n}far_t)$$

where ${}_{t+n}E_t$ is the liquidity neutral fully adjusted expected spot rate for one-period money $n$ periods in the future held by investors at time t, and ${}_{t+n}far_t$ is the fully adjusted forward rate existing at time t for one-period money $n$ periods in the future.

The term $({}_{t+n}far_t - {}_{t+n}E_t)$ in equation (2) defines a liquidity premium term which is the difference between a fully adjusted forward rate and a fully adjusted liquidity neutral expected rate. The term $({}_{t+n}r_t - {}_{t+n}far_t)$ is the difference between the observed forward rate and the fully adjusted forward rate. This term defines a market equilibrium adjustment gap due to nonspeculative factors such as those proposed by Culbertson and Modigliani and Sutch.

In the pure expectations hypothesis, investors are neutral to liquidity considerations and markets are fully adjusted to equilibrium values. Thus, under that theory ${}_{t+n}r_t = {}_{t+n}E_t$ and both $({}_{t+n}far_t - {}_{t+n}E_t)$ and $({}_{t+n}r_t - {}_{t+n}far_t)$ are not significantly different from zero. In a fully adjusted liquidity premiums model, ${}_{t+n}r_t = {}_{t+n}E_t + ({}_{t+n}far_t - {}_{t+n}E_t)$ with $({}_{t+n}r_t - {}_{t+n}far_t)$ being essentially zero. Finally, if markets also lack effective short-term adjustment, the explanation of fluctuations in observed forward rates must involve all three terms.

### A. *Expectations*

As the first step in our analysis, we formulate a model structure to explain the expectations term $({}_{t+n}E_t)$. It is assumed that expectations of future interest rates are formed according to a rational expectations process as proposed by Muth where the economic determinants of current interest rate levels form the basis for investor's expectations about future actual rates.[4]

### B. *The Real Interest Rate*

The economic determinants of interest rate levels are identified by construction of a loanable funds model largely similiar to that proposed by Sargent (1968). In his model, nominal interest rates are composed of a real component, a component reflecting inflationary expectations, and a component measuring the efficiency of market equilibrium adjustments. For a given level of real output, the real interest rate adjusts so that aggregate flows of saving are offset by flows of new investment spending. Employing this concept, we follow Sargent in formulating equilibrium saving and investment functions as follows:

$$(3) \quad I(\mathrm{t}) = I(R_e(\mathrm{t}), L_1[\Delta X(\mathrm{t})]) \qquad \frac{\partial I}{\partial R_e} < 0; \quad \frac{\partial I}{\partial \Delta X} > 0$$

$$(4) \quad S(\mathrm{t}) = S(R_e(\mathrm{t}), X(\mathrm{t})) \qquad \frac{\partial S}{\partial R_e} > 0; \quad \frac{\partial S}{\partial X} > 0$$

[3] Our framework was inspired in part by a disequilibrium model proposed by Sargent (1968).

[4] A rational expectations process based upon economic determinants of the current interest rate is not inconsistent with either the expectations hypothesis or even Meiselman's model. In the error-learning model, the current one-period spot rate is implicitly determined by economic forces of supply and demand. Thus our model makes explicit the components of the implicit assumption contained in Meiselman's model that expectations are ultimately founded upon economic variables.

where:

$R_e(t)$ = the real interest rate
$I(t)$ = desired real investment
$S(t)$ = desired real saving
$X(t)$ = aggregate output
$\Delta X(t)$ = the one-period change in aggregate output
$L_1$ = lag operator

Expression (3) reflects a distributed lag accelerator similar to that studied by Robert Eisner, modified to account for interest rate effects on investment. Expression (4) is a simple Keynesian-type saving function. To these functions, we add an exogenous governmental sector including total spending $G(t)$ and taxes $T(t)$. We define the net budgetary position $B(t)$ as:

$$B(t) = G(t) - T(t) \tag{5}$$

We also add an exogenous net exports variable $NE(t)$. The condition for interest rate equilibrium is the equality of *ex ante* saving and investment, that is:

$$I(t) + B(t) + NE(t) - S(t) = 0 \tag{6}$$

Substituting expressions (3) and (4) into this framework allows solution for the equilibrium real interest rate $R_e^*(t)$ as:

$$R_e^*(t) = f(L_1[\Delta X(t)], X(t), B(t), NE(t)) \tag{7}$$

where the partial derivatives

$$\frac{\partial f}{\partial \Delta X} > 0; \quad \frac{\partial f}{\partial X} < 0; \quad \frac{\partial f}{\partial B} > 0; \quad \frac{\partial f}{\partial NE} > 0$$

evolve from the postulated signs of the saving and investment functions, and from the role of $B(t)$ and $NE(t)$ in the equilibrium expression (6).

### C. *Inflationary Expectations*

The impact of inflationary expectations on nominal interest rates is taken to be a distributed lag function of the rate of actual price change as postulated by Irving Fisher. This formulation has also been examined empirically by William Gibson, Leonall Anderson and Keith Carlson, Yohe and Karnosky, Elliott, and John Rutledge. Sargent (1973b) has noted that a particular set of restrictions on an *IS-LM* type model is implied when the Fisherian formulation of inflationary expectations is coupled with the assumption that $R_e^*$ is constant over time. Our formulation does not make this assumption and should be free of problems on this account.

The speed of adjustment component of nominal rates is assumed to depend principally upon changes in the money supply as proposed by Wicksell. When these two components are added to the real interest rate expression (7), the complete model for current nominal interest rates $i(t)$ results. This is:

$$i(t) = f(L_1[\Delta X(t)], X(t), B(t), NE(t)) + g(L_2[Dp(t)]) + h(DMS(t)) \tag{8}$$

where $Dp(t)$ is the percent change in general prices, $DMS(t)$ is the percent change in money supply, and $L_2$ is a second lag operator. Expression (8) differs from the loanable funds model proposed by Sargent in two ways. First, a distributed lag investment accelerator replaces his single period accelerator. This modification reflects the prevalent empirical evidence that output adjustments impact on investment demand with a lag. Secondly, government expenditures and net exports have been added to complete the model and to make it correspond to the recent economic conditions reflected in the modern data used here. Sargent ignored government spending, tax, and net export impacts on equilibrium in his tests using data from 1902–40, presumably because such effects were judged to be of little significance during this earlier period.

The complete model for expected spot

rates is produced from equation (8) by specifying the structure to be linear, defining the lag distributions, and by replacing $i(t)$ by ${}_{t+n}E_t$ to reflect the hypothesis that the economic factors impacting upon current nominal rates are the same factors that form rational expectations about future nominal rates.

In the empirical tests to follow, the use of monthly data has an impact on the specification of the two lag distributions. Since high serial correlation is commonly a characteristic of monthly data, even for flexibly constrained lag distributions of the considerable length suggested by previous studies of accelerator and price expectations lags, we formulated both of the lag distributions in the following way:

$$(9)\quad L_1 = a_0[X(t) - X(t-1)] + a_1\Delta X(1,12) + a_2\Delta X(13,24) + a_3\Delta X(25,36) + a_4\Delta X(37,48) + a_5\Delta X(49,60)$$

$$(10)\quad L_2 = \frac{b_0[p(t) - p(t-1)]}{p(t-1)} + b_1 Dp(1,12) + b_2 Dp(13,24) + b_3 Dp(25,36) + b_4 Dp(37,48) + b_5 Dp(49,60)$$

where the coefficients $a_i$ and $b_i$ $(i=1, 2, \ldots, 5)$ are unconstrained, and where

$$Dp(j, j+11) = \frac{p(t-j) - p(t-j-11)}{p(t-j-11)} \quad \text{for } j = 1, 13, 25, 37, 49$$

$$\Delta X(j, j+11) = X(t-j) - X(t-j-11) \quad \text{for } j = 1, 13, 25, 37, 49$$

We may now write the model of expected future spot rates used in our empirical testing:

$$(11)\quad {}_{t+n}E_t = C_0 + C_1X(t) + C_2B(t) + C_3NE(t) + C_4DMS(t) + L_1[\Delta X(t)] + L_2[Dp(t)]$$

D. *Liquidity and Market Disequilibrium*

Our model of observed forward rates is completed by specifying determinants of the liquidity and market disequilibrium terms. Earlier work by Kessel, Van Horne, and Charles Nelson has utilized the idea that liquidity premiums are influenced by temporal changes in market interest rates or other related variables.[5] In particular, Kessel presents supporting empirical evidence that liquidity premiums are a function of current spot rates on short maturity default free debt. We test this hypothesis using our model of expectations by specifying liquidity premiums to be a function of the current one-year spot rate on *U.S.* government bonds. Thus, the first specification of the liquidity premium term is that it is proportional to current spot rates:

$$(12)\quad ({}_{t+n}far_t - {}_{t+n}E_t) = C_5(R_{t,1}); \quad C_5 \geq 0$$

where $R_{t,1}$ is the current one-year spot rate.

Van Horne has conducted empirical tests related to liquidity premiums using the error-learning framework and focusing upon forward rates rather than spot rates. He interprets his results as indicating the importance of interest rate risk, or the risk associated with fluctuations in the principal value of securities due to changes in interest rate levels.[6] Van Horne finds this risk to be inversely related to forward interest rate levels. Increases in bond prices relative to an accustomed price are assumed to increase interest rate risk essentially by increasing the probability of future price decreases. To test this hypothesis in

[5] A direct measurement of a liquidity premiums function in the context of the error-learning model has been presented in a separate work by the authors (1975).

[6] The conceptual development of interest rate risk is presented by Nicholas Kaldor and Burton Malkiel. Charles Nelson, pp. 35–36, cautions that the empirical results presented by Van Horne in his test of an interest rate risk variable are suspect due to the existence of a specification error in the original model. Further research on Van Horne's original model and extended empirical results on the interest rate risk variable are available in the authors' paper (1975).

our analysis, the liquidity premium is taken to be a function of the price of bonds having one year to maturity. That is:

$$(13)\quad ({}_{t+n}far_t - {}_{t+n}E_t) = C_6(P_{t,1});\quad C_6 \geq 0$$

The market adjustment term in expression (2) focuses upon the extent to which speculative activity maintains markets in a near-equilibrium position over time. Culbertson's work on this subject has focused on motives for investment by banks, insurance companies, and other financial institutions that potentially restrict their speculative activity to certain regions of the yield curve. More recently, Modigliani and Sutch (1967, 1968) have been concerned with the possible impact on the yield curve of changes in the proportion of *U.S.* government debt of different maturities supplied to the investment markets. In Culbertson's view, the demand for bonds by particular institutions can be expected to affect some regions of the yield curve disproportionately without such effects being transmitted along the entire curve.[7] Modigliani and Sutch point to the same type of rigidities in acceptable maturity regions, i.e., preferred habitats, as potential reasons to expect the supply of bonds of a particular maturity to push up yields in the associated maturity region by a disproportionate amount.

To obtain an approximate measure of the movements of institutional patterns of demand, we calculate a ratio of the stock of investment funds available to banks compared to that available to insurance companies. These two institutions are typically both large holders of *U.S.* government securities. Furthermore, data regularly published in the *Federal Reserve Bulletin* (see Table A37–Dec. 1974 issue for example) reveal that bank holdings of *U.S.* government securities are concentrated in predominantly short-maturity issues while insurance companies hold disproportionately large amounts of long-maturity issues. In markets that adjust quickly and completely, fluctuations in the ratio of bank to insurance company holdings should have no impact on forward market rates as the demand and supply effects will be transmitted along the entire yield curve. The specific hypothesis tested here is:

$$(14)\quad ({}_{t+n}r_t - {}_{t+n}far_t) = C_7\left[\frac{BH(\mathrm{t})}{IH(\mathrm{t})}\right]$$

where $BH(\mathrm{t})$ is the stock of bank funds invested in *U.S.* government securities at time t and $IH(\mathrm{t})$ is the stock of insurance company funds invested in *U.S.* government securities at t.

In measuring the movement in the relative supplies of debt of various maturities, we use the approach of Modigliani and Sutch by computing the proportion of debt in various maturity categories. They found the ratio of short to long debt to be among the best of a number of candidate measures of bond supply effects. We define such a measure as the ratio of the stock of bonds having less than 5 years to maturity to the stock of bonds having 10 years or greater to maturity. The split at 5 years is inspired by the availability of data and previous work by ourselves (Elliott and Echols 1976) in which the 8-year maturity region for *U.S.* government securities was found to exhibit a clear break in the speculative characteristics between the short and long regions. In a highly speculative market for governments, changes in the proportion of short to long bonds outstanding should have no explanatory power relative to forward rate movements. We test this proposition using the following hypothesis:

$$(15)\quad ({}_{t+n}r_t - {}_{t+n}far_t) = C_8\cdot\left(\frac{SG(\mathrm{t})}{LG(\mathrm{t})}\right)$$

[7] While Culbertson discusses the demand effects, Modigliani and Sutch (1966) assume these effects are unimportant as follows: "Unfortunately, the measurement of supply-demand effects poses formidable problems, even if we are prepared to limit ourselves to variations in supply, on the assumption that the demand side is not subject to significant variations" (p. 191).

where $SG(t)$ is the stock of 0–5 years to maturity $U.S.$ government bonds at t and $LG(t)$ is the stock of 10-year and up $U.S.$ government bonds at time t.

To summarize, we have now formulated an explanatory model for forward rates from expression (2) that contains as arguments rationally expected future rates (expression (11)) and may also contain liquidity influences (expressions (12)–(13)) and/or supply and demand influences (expressions (14)–(15)).

## II. Data and Empirical Results

The empirical tests of the model presented in this paper are based on month-ending yield data derived from a yield curve model developed by the authors (1975) and presented in the Appendix. The yields are produced by setting the coupon variable in the yield curve model equal to zero and computing the zero-coupon-equivalent yield for each maturity tested.[8] Details of this and other calculations are given in the Appendix.

The yield curve values enable the dependent variable in our analysis, forward rates, to be derived according to equation (1). The existence of a seasonal pattern motivated the seasonal adjustment of the raw forward rates.

An important attribute of the yield and derived forward-rate data used here is its correction for coupon effects. The correct calculation of forward rates must be based on pure rates of discount, rather than from coupon-bearing bonds, basically due to the return of capital through time associated with coupon-bearing bonds. Thus, ideally, forward rates should be calculated from yields on zero-coupon bonds. In our data, we approximate this pure discount rate by our treatment of the coupon term. The forward rates that result are free of distortions that may result from the confounding of coupon effects upon yield with pure term structure effects.[9]

The initial empirical test is conducted upon the rational interest rate expectations model component of expression (11), where the observable forward rate ${}_{t+n}r_t$ replaces the unobservable ${}_{t+n}E_t$. In the statistical estimation of (11), it is important to note that the observation on the dependent variable ${}_{t+n}r_t$ is taken at the close of trading for month t while observations on all t subscripted right-hand-side variables are taken as flows over period t or as average stocks during t. Thus, no opportunity for "feedback" of a simultaneous-equations nature is present in our results, and all same-period right-hand-side variables can be taken as predetermined with respect to the dependent variable. Behaviorally, taking the observations on ${}_{t+n}r_t$ at month end postulates that the month-ending term structure adjusts so that the cumulative flows of aggregate saving and investment during the month are brought into balance. This approach seems as reasonable as postulating an equivalent statement about month-averaged forward rates, and is clearly superior with respect to the econometric conveniences introduced by it.

The expectations model is fit for each of the ten forward rates, with the results shown in Table 1. These results show a generally high degree of forward rate explanation implying our rational expectations model has useful explanatory properties. In addition, the corrected $R^2$ values increase with more distant forward rates, revealing that the expectations model explains a somewhat larger proportion of the fluctuation in forward rates as those rates become more distant.[10] This pattern is in-

[8] The range of observed coupon values in our yield data is from $2\frac{1}{2}$ percent to 7 percent.

[9] Previous empirical studies that have used David Durand's data or U.S. Treasury yield data are subject to the difficulty associated with intermixing bonds of various coupons and rates in samples used to calculate yield curves.

[10] This is not merely the result of differences in the

[e] Net exports $NE(t)$

[f] Government deficit $B(t)$

terpreted to suggest that expectations about future spot rates play a slightly more significant role in forward rate determination the more distant the forward rate. At first glance this result seems the opposite of that developed by Meiselman, who found the fit of the error-learning model to decrease over the maturity range from 1 to 8 years. However, the two are not necessarily incompatible. Meiselman has shown that error learning is less important for more distant rates; more important for closer rates. Our results suggest rational expectations are slightly more important for more distant rates; less important for closer rates. The two sets of results are not inconsistent with the suggestion that more weight passes from error-learning influences to rational expectations influences as more distant rate expectations are formulated.

The variables in our expectations model generally produced measured coefficients that are consistent with their a priori role in the model. We find real output to have a uniformly negative effect on interest rate expectations reflecting its role in the saving function. The governmental deficit is found to have the expected positive effect in all but the two longest maturities, and the investment accelerator $L_1[\Delta X(t)]$ and price expectations $L_2[Dp(t)]$ terms are found to each have positive effects as hypothesized. The impact of net exports on interest rate expectations are found to be weakly negative for the first three forward rates and increasingly positive thereafter. This may reflect the initial monetary effect of a change in net exports, which is expected to be negative, followed by the longer-run expectation of rising rates due to the increase in investment-like expenditures and the attendant positive impact on forward rates.

The money supply term is negative in

total variability or mean value of the various forward rate series, for equation (A1) of the Appendix shows both the mean and the standard deviation to be approximately constant over the entire forward rate sample.

[a] Significant at 1 percent level.

all but the initial period where it is positive and insignificantly large. This prevalent negative influence of current money supply change on expected interest rates is consistent with results obtained by Sargent (1968) in his empirical tests, and consistent generally with the theoretical role of money in the present model structure. In addition, while lacking in statistical significance, we find the role of the monetary effect to grow somewhat with more distant rate expectations. Taken together, these results suggest that the variables in our rational expectations model work individual effects that are consistent with their a priori roles in the loanable funds framework.

The second sets of tests explore the impact of adding the liquidity premium and institutional supply and demand terms to the expectations model. Table 2 shows the estimated coefficients and goodness-of-fit statistics associated with the separate addition to the interest rate expectations model structure of each of the two variables used to test for liquidity premiums. The re-estimates of the coefficients in the expectations model to which these terms are added are not shown to simplify the table. However, they do not differ measurably from the results shown in Table 1 with the exception discussed below.[11] Standard errors in Table 2 are directly comparable with those in Table 1 since the dependent variable is identical.

Both current 1-year spot rates and 1-year bond prices are found to have the sign proposed by Kessel with the exception of the 20-year rate, where the effect fades in significance. Thus, they are inconsistent with Van Horne's hypothesis. Increases in

[11] These details and similar details associated with Tables 2 and 3 can be provided to the interested reader upon request.

current spot rates or declines in bond prices are found here to systematically increase forward rates, presumably due to their role in influencing liquidity premiums. $F$-tests of the additional explanatory power associated with each term are shown in Table 2. These results show that either variable tested adds substantial explanatory power to that of the basic expectations model. This result is further support for Kessel's hypothesis on the role of current spot rates in determining liquidity premiums. However, it is not possible to assign the influence of current spot rates uniquely to liquidity premium effects, due to the possible reflection of expectational determinants in current short-term rates. In this respect, we find that the impact of the government deficit position changes signs and declines in significance when the spot rate or bond price is added to the equation. This indicates a collinear pattern between the two, and more broadly suggests that the same type of future interest rate expectational determinants represented by the deficit position are contained in current spot rates. Even so, the information contained in spot rates is sufficiently independent to cause this term to make a statistically significant contribution to the basic expectations model.

The magnitude of the impact of both the spot rate and bond price terms declines somewhat as the forward rate horizon is lengthened. This produces a suggestion that the liquidity related effects we have measured depend somewhat upon the extent to which rational expectations explain forward rate levels. At 1-year forward rates, when the rational expectations model explains 87.2 percent of the forward rate fluctuations, both the liquidity premium variables exert their largest effects, while at 20-year forward rates where rational expectations account for 94.5 percent of the fluctuation in forward rates, the liquidity terms exert their smallest and least significant effects. Thus, our results suggest the perception of a liquidity premium as a price paid for the unpredictability of future rates, i.e., as the markup over expectations that investors require due to the incompleteness with which rational expectations successfully account for movements in forward rates.

Finally, the spot rate term appears to be slightly better than the bond price in its explanatory power. The $F$-values for the addition of this variable are a little higher than for the bond price, while both have a nearly identical effect in reducing the somewhat questionable degree of autocorrelation associated with the basic expectations equation. In considering the market equilibrium variables, we proceed by using the spot rate to reflect liquidity effects on forward rates.

We consider the market equilibrium adjustment effect in two ways: in relation to the basic equation, and in relation to the basic equation with the spot rate term added. Although the results of these two tests lead to similar conclusions and interpretations, differing primarily in the magnitude of the $F$-statistics, there is reason to prefer the results from the the latter structure including the spot rate term. Our analysis to this point has suggested that both rational expectations and the liquidity premium variable play influential roles in forward rate determination. Given the nature of these variables, we can only interpret their role as influencing equilibrium positions. In considering possible influences of market adjustment imperfections, the most complete equilibrium model is the most appropriate. Thus, we consider the market adjustment variables in combination with the expectational and liquidity premiums portions of the model.

The results of adding the institutional demand and bond supply variables to the expectations and liquidity premium structure are shown in Table 3. The ratio of

bank to insurance company holdings shows the expected negative sign in all cases but the 20-year case where the relationship is measured to be weak and in the opposite direction. The indication is that an increase in the proportion of investment funds held by banks relative to insurance companies systematically pushes down forward market rates, presumably due to their short preferred habitat. Furthermore, the statistically significant $F$-values associated with addition of the bank to insurance company ratio indicate that explanatory significance attaches to fluctuations in this ratio that are not contained in either the expectations model or the liquidity term. In addition, the value of $C_7$ declines in impact as forward rates become more distant, indicating that positive shifts in the proportion of bank investment funds has a somewhat greater impact on closer forward rates than on more distant forward rates.

The ratio of short to long maturity bond supplies also shows a measured sign consistent with its a priori role in all but the longest maturity cases. Thus an increase in the proportion of short maturity debt outstanding has a small positive impact on forward market rates, increasingly for more current forward rates than for more distant rates. However, this term in no case makes a statistically significant contribution to the explanation of forward rate movements, as the $F$-values are insignificantly small. In fact, the bond supply term actually detracts from the level of additional explanation associated with the bank to insurance ratio when the two terms are added to the model as shown in the third set of results in Table 3. These results are in basic agreement with the

studies of bond supply made by Modigliani and Sutch in not finding a substantial explanatory role for such ratios. We conclude that shifts in institutional participation in bond markets between banks and insurance companies are significant in forward rate determination suggestive of the operations of preferred habitats for banks and/or insurance companies. However, evidence has not been obtained that supplies of short vs. long bonds have a significant impact on forward rates.

### III. Rational Interest Rate Expectations and Preferred Habitats

Our rational expectations model for expected future equilibrium interest rates given by expression (11) can be integrated with the basic model structure of Modigliani and Sutch to develop new evidence on the usefulness of their approach in explaining yield spreads, and on the potential role of the earlier defined bond supply and bank-insurance company holdings terms in contributing to the explanation of yield spreads. Modigliani and Sutch's basic model is a statement of the equality of holding period returns across various maturities. It is given as follows:

$$(16) \quad R_{n,t} = R_{m,t} - [\textit{Expected Capital Gain}] + F_t$$

where $R_{n,t}$ is the market yield on $n$-period money, where $m$ is the minimum holding period, and where $F_t$ is the net effect of relative supply factors. In Modigliani and Sutch's work, the expected capital gain term in (16) is assumed to be proportional to the expected fall in the yield on a present $n$-period bond over the given holding period of $m$ length. This gives:

$$(17) \quad R_{n,t} = R_{m,t} - \beta[R_{n,t} - {}_{t+m}E_{n-m,t}] + F_t$$

where ${}_{t+m}E_{n-m,t}$ is the rate on $n-m$ period money expected to exist $m$ periods in the future, held as of time t.

Modigliani and Sutch replace the terms in the bracket of expression (17) by a distributed lag on short rates. The development of the present rational expectations model for expected rates and the positive support we have obtained for its structure enables analysis of an alternative approach. We may instead insert a direct estimate of ${}_{t+m}E_{n-m,t}$ into (17) obtained by regressing an actual rate upon the right-hand-side determinants of the rational expectations generating function of expression (11) and computing the value of ${}_{t+m}E_{n-m,t}$ from the estimated coefficients.

Use of a direct estimate of the expected rate term in expression (17) leaves the $R_{n,t}$ term on both sides of the equation. Solving for this term and assuming $F_t$ to be proportional to various market disequilibrium measures $X_t$ according to a proportionality constant $\alpha$ gives:[12]

$$(18) \quad R_{n,t} = k_1 R_{m,t} + k_2 \cdot {}_{t+m}E_{n-m,t} + k_3 \cdot X_t$$

$$\text{where } k_1 = \frac{1}{1+\beta}, \quad k_2 = \frac{\beta}{1+\beta}, \quad k_3 = \frac{\alpha}{1+\beta}$$

To estimate (18) we must select the maturity $n$ and the holding period $m$. Modigliani and Sutch did most of their work using a sample of bond yields containing a mixture of securities in the 10 to 15-year maturity range for the dependent variable and with a variety of differing coupons. For consistency with their maturity, we use a 12-year government yield obtained from our zero-coupon equivalent data. We consider a 90-day holding period ($m=1/4$) corresponding to Modigliani and Sutch's holding period. Accordingly, in estimating coefficients for the calculating of ${}_{t+m}E_{n-m,t}$, we use the one-quarter ahead yield on a

[12] Inspection of the expressions for $k_1$, $k_2$, $k_3$ shows an implied constraint on the value of $\beta$ in these regressions. We have not imposed this constraint in our empirical tests in order to observe the extent to which the data exhibit the constraint implied by the model. We find the model constraint on $\beta$ is not well characterized by the data.

bond of 11 years 9 months to maturity for the left-hand side of expression (11). Similarly, $R_{m,t}$ is approximated by a 90-day Treasury Bill rate as in the Modigliani-Sutch study. Finally, to compare our results directly with those of Modigliani-Sutch, we subtract $R_{m,t}$ from both sides of the equation, leaving the dependent variable defined as a spread between the 12-year and 90-day rate, and redefining the coefficient $k_1$ in expression (18) to be $(k_1-1)=k_1'$ as is done in the Modigliani-Sutch estimates. Thus, we estimate:

$$(19) \quad S_t = k_1' R_{m,t} + k_2 \cdot {}_{t+m}E_{n-m,t} + k_3 \cdot X_t$$

where $S_t$ is the spread.

To measure the effects of bond supply, we use the earlier defined ratio of short to long *U.S.* government bonds outstanding, and in addition we follow Modigliani and Sutch in the use of the proportion of short debt (5 years and under) to total debt and the proportion of long debt (10 years and over) to total debt. To these three representations of their bond supply measures, we add parallel measures of institutional participation due to our earlier results: (a) the ratio of bank investment funds to total debt, (b) the ratio of insurance company investment to total debt, and (c) the earlier-defined ratio of bank-to-insurance company investment funds.

These measures are combined into three alternative measures of the $F_t$ influence in expression (16):

$$\text{(Short Funds)} \quad F_t = k_{3,D} \cdot \frac{DH(t)}{T(t)} + k_{3,S} \cdot \frac{SG(t)}{T(t)}$$

$$\text{(Long Funds)} \quad F_t = k_{3,D} \cdot \frac{IH(t)}{T(t)} + k_{3,S} \cdot \frac{LG(t)}{T(t)}$$

$$\text{(Short-Long Ratios)} \quad F_t = k_{3,D} \cdot \frac{BH(t)}{IH(t)} + k_{3,S} \cdot \frac{SG(t)}{LG(t)}$$

where $T(t)$ is the total outstanding *U.S.* government securities and other variables are as defined earlier. The results of estimating these three equations plus the basic equation where $F_t=0$ are given in Table 4. In these estimations, an intercept term $k_0$ has been added to provide a weak test of this aspect of the model specification. In no case was it found to be significantly different from zero in magnitude, a result that is consistent with the model structure of expression (19). The estimated values of $k_2$ provide strong support for the role of the expected future rate variable with which it is associated, as this coefficient is highly significant in each of the model specifications in which it appears. In addition, the impact of the short-term

TABLE 4—MODIGLIANI-SUTCH MODEL

*Note:* Equations are estimated by generalized least squares with $\rho=.60$ due to the highly autoregressive nature of the ordinary least squares (*OLS*) error term. Numbers in parentheses are computed $t$-values. Standard errors are given in ($10^{-3}$) units of the dependent variable. $F$-values are for the significance of adding the $k_{3,D}$ and $k_{3,S}$ terms.

[a] Significant at the 1 percent level.

rate on the spread is negative as hypothesized and statistically significant in each equation. This is also consistent with the estimates of Modigliani-Sutch (1966). Furthermore, the magnitude of the estimated coefficients is quite comparable in the two cases ranging from about $-.65$ to $-.77$ in our case to about $-.69$ in the Modigliani-Sutch case.

The $F$-values given in Table 4 show the significance of the increase in explained variation associated with adding the alternative specifications of the $F_t$ influences to the basic equation. For all three specifications, the $F$-values are significant beyond the 1 percent level, indicating the supply and demand measures have substantial explanatory significance. The long-short ratio model provides the greatest effect in this regard, indicating this form of the variables to be somewhat superior. However, the measured direction of effect associated with each supply and demand variable is in the wrong direction vis-à-vis its underlying hypothesized role. This result is quite similiar to that found by Modigliani and Sutch (1966, p. 191); indeed our coefficient estimates are in the same direction as comparable estimates of theirs in all but the case of the supply of long bonds variable.

In interpreting the original Modigliani-Sutch results, it might be suggested that the omission of measures of institutional demand contributed to the peculiar results obtained for the supply variables; however, we find here that while the demand variables used are significant, their presence does not alter the result obtained for the supply ratios. Thus, it is necessary to look elsewhere to find the explanation for the conflict between the a priori role and the empirical results for the supply terms.

## IV. Conclusion and Implications

An explanatory model for forward rates has been developed in this research that enables analysis of the contribution of expectational determinants, liquidity premium influences, and institutional demand and bond market supply effects upon fluctuations in forward rates. A rational expectations model for future expected interest rates has been developed from a loanable funds framework. The results of empirical tests of this rational expectations structure show it to have consistently high $R^2$ values and individual coefficient signs that are consistent with the a priori rôle of each variable in the underlying loanable funds model of interest rate determination. These results are supportive of the relevance of the model in measuring rational interest rate expectations.

When spot rates are added to the expectations model structure to measure liquidity premium effects, the degree to which fluctuations in forward rates are explained is significantly increased. The additional expansion of the model to include the ratio of bank to insurance company investment funds further significantly increases the explanation of forward rate fluctuations. However, the explanatory role of relative bond supplies in forward rate explanation is not confirmed in a similar experiment. Taken together these results suggest an important incremental role for a liquidity-premiums–related measure and a measure of institutional bond demand in affecting forward rate fluctuations independent of the significant role associated with rationally expected future rates.

The present model of rationally expected future interest rates is used in the model structure of Modigliani and Sutch to obtain new evidence on the impact of institutional demand and bond supply upon yield spreads. Unlike the results obtained in our model of forward rates, empirical evidence with respect to fluctuations in the yield spread between 12-year government securities and the Treasury Bill rate is not consistent with the a priori

role assigned to these variables.

One possibility for this divergence in logical versus empirical results is that yield spreads are not a sufficiently sensitive vehicle for observing such effects. While yield spreads show the total change in yield over a given maturity range, forward rates approximate the movement in the slope of the yield curve over particular short regions of the curve. Thus, our forward rate model results could be taken to suggest that institutional demand patterns influence the instantaneous slope of the yield curve at a number of points along the curve. At the same time, the tests of the Modigliani-Sutch model indicate that raw yield spreads over a fixed maturity range are not similarly influenced.

We have not produced evidence that suggests that specific debt management strategies of supplying bonds of particular maturities are likely to influence either spreads or forward rates. However, our results support the suggestion that policy actions that alter the relative amounts of funds available to institutions such as banks and insurance companies might well be expected to impact on forward rates and thus upon the relative shape of the yield curve. Thus, policy actions having the effect of reducing the stock of investment funds available to banks relative to insurance companies have been found to importantly associate with increases in forward rates, which indicates a movement of the associated yield curve toward a more steeply rising or less steeply falling position, particularly in the earlier maturity regions.

## Appendix—Derivation of Zero-Coupon Equivalent Yields

*Dependent Variable:* Seasonally adjusted one year forward rate: ${}_{t+n}r_t$ where t is the date of observation, and $n$ = years after t that the forward rate applies.

The original data source for the dependent variable is monthly observations on the market price of U.S. Treasury bonds outstanding for the period 1964–1 through 1972–12, taken on the last trading day of each month. Yields are calculated from these prices, and are used to fit equation (A1), giving monthly yield curves on *U.S.* government bonds:[13]

$$\text{(A1)}\quad (1 + R_{t,n}) = C_0 \cdot C_1^{(1/n)} \cdot e^{C_2(n)} \cdot e^{C_3(x)} \cdot e^{\epsilon}.$$

where:

$R_{t,n}$ = the yield to maturity on an $n$-period bond, observed at time t,
$n$ = the time to maturity,[14]
$x$ = the coupon value,
$\epsilon$ = a white noise error term, and $C_0$, $C_1$, $C_2$, and $C_3$ are estimated coefficients.

The unadjusted forward rate at date t is derived from these yields by evaluating equation (1) for different values of $n$. The unadjusted forward rates were tested for a significant seasonal component using the Bureau of Census X-11 variant seasonal adjustment program.[15] Because a significant seasonal factor was found in every forward rate, all of the forward rate data were seasonally adjusted. The equivalent yield for a zero-coupon rate is found by setting $x$ equal to zero.

*Exogenous Variables*

$X(t)$ = Real *GNP*, expressed monthly by application of the spline function method as defined by the National Bureau of Economic Research (*NBER*) in their TROLL system library.[16] Source: U.S. Office of Business Economics (*OBE*).

[13] This yield curve model is developed and tested in the authors' paper (Echols and Elliott). The yield curve model is derived from the framework of term structure theory. It shows an average $R^2$ value of .85 over the 108 sets of bond price data used in the tests.

[14] The number of bonds outstanding at any date is a function of the date. Thus, for example, there are 35 observation values in January 1964 and 18 observed values in December 1972.

[15] The potential impact of a seasonal factor on interest rates is motivated by results obtained by Stanley Diller.

[16] The method uses Newton's divided-difference interpolation formula to obtain a system of equations for the second derivative of the spline function, evaluated at the knots. These equations are reduced so that they use only the second derivative and second derivative differences. Since the second derivative is linear and the start and end values are known to equal zero, the system can be solved.

$p(t)$ = *GNP* price deflator, expressed monthly by the *NBER* TROLL spline method. Source: *OBE*.

$B(t)$ = Total government purchases less total tax revenues, expressed monthly as above. Source: *OBE*.

$NE(t)$ = Net export balance, expressed monthly as above. Source: *OBE*.

$MS(t)$ = Monthly real money supply, defined as currency and demand deposits ($M_1$) divided by $p(t)$. Source for $M_1$: Federal Reserve System (*FRB*).

$R_{1,t}$ = Average market yield on 1-year U.S. Treasury Bills observed monthly. Source: *FRB*.

$P_{1,t}$ = Average monthly price on a zero-coupon equivalent 1-year bond, observed monthly, calculated according to the following:

$$P_{1,t} = (1 + R_{1,t})^{-1} \tag{A2}$$

$BH(t)$ = Monthly stock of bank funds invested in *U.S.* government securities at time t. Source: *FRB*.

$IH(t)$ = Monthly stock of insurance company funds invested in *U.S.* government securities at time t. Source: *FRB*.

$SG(t)$ = Monthly stock of outstanding 0–5 years to maturity *U.S.* government bonds at time t. Source: U.S. Treasury Department (*TB*).

$LG(t)$ = Monthly stock of outstanding 10-year-and-up years to maturity *U.S.* government bonds at time t. Source: *TB*.

# The Value of Human Life in the Demand for Safety

*By* BRYAN C. CONLEY*

The economics of safety is one of the interesting new areas to which economic theory is currently being applied.[1] Topics of analysis range from the estimation of costs of alternative safety programs to models of consumer choice incorporating safety aspects. From either an individual's or society's point of view, presumably there are safety precautions (or risks) worth taking depending upon costs (or benefits), the probabilities involved, wealth, risk aversion, and other factors.

The most critical safety decisions are those concerning the possibility of accidental loss of life. For a sufficiently small probability, there is a conceptual "value of human life" which, multiplied by the probability, will yield the maximum payment a person would make for the stated improvement in survival.

For government safety programs, the benefit per statistical life saved would be the average of the affected population's values of human life plus the value of any externalities. However, traditional benefit-cost analysis has relied upon the "human capital" approach, in which the benefit is the discounted earnings (reflecting productivity) of the affected population. Although more data are available on the human capital approach, the "willingness-to-pay" method is theoretically superior. So far no one has with success theoretically linked the two values, especially in terms of order. Indeed, some believe there is no necessary relationship.[2] Neither has a model been developed in which choices of specific commodities are involved and in which the probability of living is affected by such choices.

The purpose of this article is therefore twofold: 1) to extend the traditional model of individual maximization to include the effects of choices involving a changed probability of living; and 2) to determine the value of human life with reference to an individual's wealth and utility function characteristics.

In Section I, a deterministic model of individual optimization (except for time of death) is developed. The individual maximizes expected utility where the probability of death is under his control. After developing several forms of equilibrium conditions and interpreting them, I analyze the effect of relaxing two of the assumptions and summarize theoretical relationships published elsewhere. In Section II, the model is applied to the demand for safety, and implications are drawn for demand studies and for measurable utility.

The principal conclusion of this study is that for income above some undetermined but presumably low level, the value of life

* Assistant professor of business economics, Graduate School of Business, University of Southern California. Thanks are due Michael Intriligator, Finis Welch, and John Hambleton for helpful comments on an early draft, and an anonymous referee on a later draft. The Center for Public Economics, San Diego State University provided secretarial assistance. I am, of course, responsible for any errors.

[1] See Jack Carlson, Gary Fromm, Lester Lave, E. J. Mishan, Walter Oi, Thomas Schelling, and Joseph Spengler.

[2] Schelling states: "There is no reason to suppose that what a man would pay to eliminate some specific probability, *P*, of his own death is more than, less than, or equal to *P* times his discounted expected earnings. In fact there is no reason to suppose that a man's future earnings, discounted in any pertinent fashion, bear any particular relation to what he would pay to reduce some likelihood of his own death" (p. 149).

is greater than discounted earnings, and in early and middle adulthood, greater than discounted consumption.

## I. The Model

My aim is to separate the other uncertainties of living from those associated with risk of loss of life.[3] Thus it is assumed that all relevant variables and functional relationships are known, the only uncertainty being the actual time of death. Let a person be infinitely sensitive; have full information of all prices, probabilities, and his preferences; and be interacting in competitive markets with zero transaction costs.[4] Let him choose among life histories such as to maximize expected lifetime utility, the von Neumann-Morgenstern postulate. The objective function is of the form[5]

$$E(U) = \sum_{t} \delta(t)u(\cdot)p(\cdot) \tag{1}$$

whereby expected lifetime utility is separable into discounted single period utilities, $\delta(t)$ is the utility discount function, $u(\cdot)$ is a single period utility function, and $p(\cdot)$ is the probability of being alive.

The unit of analysis will be the decision or control variable $x^{it} \geq 0$, which is the value of activity $i$ in time period t. (Superscripts designate time and activity indices; subscripts indicate partial derivatives.) An activity will be called consumption if the consumer must expend cash outlays and production if it results in cash income.

I assume an infinite planning horizon.[6] Time 0 is the beginning of decision making at age $\tau$; and for time indices T and t, $0 \leq \mathrm{T} \leq \mathrm{t}$.

### *A. The Objective Function*

The utility discount function $\delta(\mathrm{t})$ shall take the form that R. H. Strotz proved was necessary for consistent multiperiod consumer behavior; thus

$$\delta(\mathrm{t}) \equiv \delta^{\mathrm{t}} \equiv \left(\frac{1}{1+s}\right)^{\mathrm{t}} \tag{2}$$

where $s$ is the subjective time discount rate of utility.

The single period time-invariant utility function shall be

$$u(\cdot) = u(x^{1t}, x^{2t}, \ldots, x^{nt}) = u(X^t) \tag{3}$$

where $X^t$ is the vector of activities in period t. Making the simplest of assumptions, I assume no externalities: none of the $x^{it}$ enter others' utility functions; neither do any of others' activities enter $u(\cdot)$. Thus there is no family that cares about a person's life and no desire to leave an estate is allowed. Below I shall relax this assumption.

The utility function $u$ is assumed to be strictly concave, i.e., $u'' < 0$; we will not require either $u' > 0$ or even $u > 0$ for all values of every activity. Assume $u(0, 0, \ldots, 0) \equiv u^* = 0$; that is, the utility of not living is zero.[7] Likewise it is assumed there are some $X^t > 0$ for which $u(X^t) = 0$.[8] Thus

[3] This approach is also adopted by Menahem Yaari.

[4] Oi's model also depends on these assumptions.

[5] Expressing lifetime expected utility in continuous form appears to be impossible due to difficulties in expressing the $p$ function. In a related paper, Morton Kamien and Nancy Schwartz construct a similar model for optimal maintenance of a machine. They assume that maintenance expenditures affect only the immediate probability of machine failure, which is more restrictive than my initial behavioral assumption contained in equation (4) below. Subsequently in equation (9) attention is restricted to activities which immediately affect probability of survival. Had I so restricted the assumptions initially, the model could have been developed in an optimal control framework with identical results.

[6] For convenience, no upper bound on a lifespan is assumed. No arbitrary upper bound on an individual's planning horizon can be postulated, as there is no future time for which $p(\cdot) = 0$ by necessity. Although an infinite life has not yet been experienced, the history of mortality cannot logically negate its possibility. Also, future medical advances may make an infinite life biologically possible.

[7] This assumption is basically atheistic in orientation. Below, I shall explore the implications of altering this assumption.

[8] Some utility functions such as $u = \log x$ and $u = C_0 - x^\gamma$ have this property; this level of consumption may be considered a subsistence bundle of goods, although

$u$ is determinable up to a multiplicative positive constant.

The probability-of-living function $p(\cdot)$ through period t, conditional on being alive at the beginning of period T, is[9]

$$(4) \quad p^{Tt}(T, t, x^{1T}, x^{2T}, \ldots, x^{nT}, x^{1T+1}, x^{2T+1}, \ldots, x^{nT+1}, \ldots, x^{1t}, \ldots, x^{nt}) \equiv p^{Tt}(T, t, {}_{Tt}X)$$

where ${}_{Tt}X$ is the vector of $X^k$ from time T to t; $p^{Tt}(\cdot)$ is an objective conditional probability function known to all participants. Death of a person at the end of a given period may be thought of as due to the "state of nature" reacting with his activities, where the state of nature is not perfectly forecast. Note that $p^{0t} = p^{0T}p^{Tt}$ and $0 \leq p^{Tt} < 1$ for all T and t.

In summary, the total expected lifetime utility function to be maximized at any period T is

$$(5) \quad U^T = E(U)^T = \sum_{t=T}^{\infty} \left(\frac{1}{1+s}\right)^{t-T} u(X^t)p^{Tt}(T, t, {}_{Tt}X)$$

### B. Constraints

The monetary constraint requires that expected discounted lifetime consumption $C$ equal expected discounted lifetime labor income $Y$ plus wealth $W$ at T: $C^T = Y^T + W^T$, or

$$(6) \quad \sum_{t=T}^{\infty} \left(\frac{1}{1+r}\right)^{t-T} \sum_{i=1}^{n} \$^{it}x^{it}p^{Tt}(T, t, {}_{Tt}X) - W^T = 0$$

where $r$ is the market interest rate (lending and borrowing rate, assumed constant indefinitely), and $\$^{it}$ is the monetary value associated with each unit of $x^{it}$ such that $\$^{it} > 0$ when $x^{it}$ is a consumptive activity and $\$^{it} < 0$ when $x^{it}$ is productive.[10]

In full-information, competitive, costless markets such a constraint is feasible, since one can contract with an insurance company in period T to engage in activities ${}_{T\infty}X$, turning over all wealth and future labor income and receiving an allowance for contractual consumption expenditures. Therefore if (6) holds, the expected value at T of the company's receipts will equal the expected value at T of its expenditures, a contract it would write given the foregoing assumptions.

The above contract is similar to the "commodity-options" of Kenneth Arrow and the "actuarial notes" of Menahem Yaari. The purpose of the contract is not to provide for others' well-being upon one's death, but rather to expand one's expected lifetime utility.[11] In effect when one's past consumption exceeds one's past income, the insurance upon death pays off one's debt. It is not "full insurance"[12] because one is not indifferent as to whether or not the "event" occurs.

Such a contract is optimal (see Arrow), even though the probabilities are affected by one's behavior, because the company is aware of such behavior and adjusts its contractual allowances accordingly. The models of Isaac Ehrlich and Gary Becker, Walter Oi and Lester Lave incorporate the assumption of full information which leads to optimal insurance coverage.[13] Thus, as

life is possible at a lower level of consumption. If expected lifetime utility $U^T$ is negative, that is, life is less desirable than being dead, we assume a person commits suicide.

[9] Equation (4) may be considered a production function linking the probability of survival to various inputs. However it differs from most production functions in that the functional relationship is behaviorally unique to each individual.

[10] This constraint was used by Yaari and Nils Hakansson.

[11] Given that an individual wishes to leave no estate, a comparable annuity program is the optimal method of providing for retirement. Even if such a contract is not entered into, all of the subsequent conclusions are identical if a person can borrow against future earnings secured by term insurance.

[12] Isaac Ehrlich and Gary Becker state: "Full insurance can be identified with full coverage of potential losses" (p. 627n).

[13] Lave states: "A liability insurer would be motivated

Ehrlich and Becker point out, the "moral hazard" problem is eliminated.

In complete form the optimization equation (at T=0 and assuming $W^0=0$) becomes

$$(7)\quad \underset{[x^{it}]}{\mathrm{Max}}\ U^0=E(U)^0 = \sum_{t=0}^{\infty}\left(\frac{1}{1+s}\right)^t u(X^t)p^{0t}(0,\text{t},{}_{0t}X) - \lambda^0\left[\sum_{i=1}^{\infty}\left(\frac{1}{1+r}\right)^t\sum_{t=0}^{n}\$^{it}x^{it}p^{0t}(0,\text{t},{}_{0t}X)\right]$$

*C. Optimization*

The optimization of (7) for any activity $x^{iT}$ leads to the first-order condition (for an interior maximum):

$$(8)\quad \left(\frac{1}{1+s}\right)^{T}u_{iT}p^{0T}+\sum_{t=T}^{\infty}\left(\frac{1}{1+s}\right)^{t}u^{t}p_{iT}^{0t} -\lambda^{0}\left[\left(\frac{1}{1+r}\right)^{T}\$^{iT}p^{0T} + \sum_{t=T}^{\infty}\left(\frac{1}{1+r}\right)^{t}\sum_{k=1}^{n}\$^{kt}x^{kt}p_{iT}^{0t}\right]=0$$

Concavity assures the second-order conditions will be met.

This paper is concerned with those safety decisions which have the characteristic that they affect the current probability of living, but, if one survives, do not affect later conditional probabilities of survival.[14] Thus at the margin the change in the probability of survival through t of an activity undertaken in T is the probability of survival from 0 to $\dot{T}$ times the changed probability of survival through T times the conditional probability of survival from T through t. Thus

$$(9)\qquad p_{iT}^{0t} = p^{0T}\cdot p_{iT}^{TT}\cdot p^{Tt}$$

Expected lifetime net consumption at time T is

$$(10)\quad \sum_{t=T}^{\infty}\left(\frac{1}{1+r}\right)^{t-T}\sum_{i=1}^{n}\$^{it}x^{it}p^{Tt} = C^T - Y^T$$

Let $V^T$ equal net labor income; $V^T=Y^T-C^T$. Therefore $V^T$ is the expected discounted net receipts of the insurance company from its contract. Although the actuarial value of the contract is zero at time 0, if a person consumes more than he earns in early adulthood (a likely result of the "hump savings" type of optimal consumption), then the insurance company has paid out more than it has received, and therefore expected future net receipts must be positive. The value $V^T$ represents the net loss to others (here the insurance company) from death at T.

Next the Fisherian interperiod equilibrium equation is introduced,

$$(11)\qquad \lambda^T = \lambda^0\left(\frac{1+s}{1+r}\right)^T$$

where $\lambda^T=\partial U^T/\partial W^T$, the marginal utility of wealth at T. Yaari has shown (11) holds for decisions made under uncertainty when insurance is available.

Substituting (5), (9), (10), and (11) into (8) and dividing by $p^{0T}$ yields

$$(12)\quad u_{iT} = -\,p_{iT}^{TT}U^T + \lambda^T[\$^{iT} - p_{iT}^{TT}V^T]$$

The interpretation of (12) for $u_{iT}>0$, $p_{iT}^{TT}<0$, and $\$^{iT}>0$ is as follows: in equilibrium, the marginal utility of activity $i$ must equal the sum of the expected loss of lifetime utility $-p_{iT}^{TT}U^T$, plus the marginal utility of the sum of the monetary cost of

to determine the *total* cost of each safety-related act; it would be motivated to gear its premium schedule to the total cost of each safety-related act and so internalize the entire cost of the act. With liability laws, the reduction in my insurance premium stemming from fixing my brakes would reflect the cost to the people I was likely to strike as well as the cost to my property. This premium would be of the correct size to motivate an optimal level of safety" (p. 520).

[14] Many activities such as medical checkups, smoking, nonfatal injuries, and body care affect future conditional probabilities of living. The equilibrium conditions for such activities will not be explored further.

activity $i$ and the change in expected net labor income $\lambda^{T}(\$^{iT}-p_{iT}^{TT}V^{T})$.

Rearranged, (12) becomes

$$(13)\qquad \lambda^{T}=\frac{u_{iT}+p_{iT}^{TT}U^{T}}{\$^{iT}-p_{iT}^{TT}V^{T}}$$

If $p_{iT}^{TT}=0$, (13) becomes $\lambda^{T}=u_{iT}/\$^{iT}$, the familiar equilibrium condition.

Equation (13) may be further manipulated to generate a more interesting result. Recognizing that marginal utility of lifetime consumption equals the marginal utility of lifetime wealth,[15] even though not all of an exogenous increase in wealth would be used for future consumption, we have $\lambda^{T}\equiv\partial U^{T}/\partial W^{T}=\partial U^{T}/\partial C^{T}$. Dividing (12) by $\lambda^{T}$ and rearranging yields[16]

$$(14)\quad \$^{iT}-p_{iT}^{TT}\left(\frac{U^{T}}{\partial U^{T}/\partial W^{T}}+V^{T}\right)=u_{iT}/\lambda^{T}$$

The term $U^{T}/(\partial U^{T}/\partial W^{T})$ may be manipulated to yield

$$(15)\quad \frac{U^{T}}{\partial U^{T}/\partial W^{T}}\equiv\frac{C^{T}}{\dfrac{\partial U^{T}}{\partial C^{T}}\dfrac{C^{T}}{U^{T}}}\equiv\frac{C^{T}}{\alpha^{T}}\equiv L^{T}$$

where we define $\alpha^{T}\equiv(\partial U^{T}/\partial C^{T})/(C^{T}/U^{T})$, which is the lifetime consumption elasticity of lifetime utility, and $L^{T}\equiv C^{T}/\alpha^{T}$. Substituting (15) into (14) and rearranging yields this alternative formulation for the equilibrium condition:

$$(16)\qquad \lambda^{T}=\frac{u_{iT}}{\$^{iT}-p_{iT}^{TT}(L^{T}+V^{T})}$$

which is similar to (13) except that the term $p_{iT}^{TT}U^{T}$ in the numerator of (13) has been incorporated in the denominator of (16) as $-p_{iT}^{TT}L^{T}$.

### *D. Interpretation*

Before interpreting (16), I shall interpret the term $H^{T}\equiv L^{T}+V^{T}$ which appears in all equilibrium equations at time T. Here it is claimed that $H^{T}$ represents the *value of life saving* to a person appropriate to valuing safety issues.

This claim may be verified by multiplying (16) by $\$^{iT}-p_{iT}^{TT}H^{T}$ to derive

$$(17)\qquad \lambda^{T}(\$^{iT}-p_{iT}^{TT}H^{T})=u_{iT}$$

For a pure safety activity, $u_{iT}=0$ and therefore

$$(18)\qquad \$^{iT}=p_{iT}^{TT}H^{T}$$

That is, the amount the individual will pay for the pure safety activity is the changed probability of living times $H^{T}$; therefore $H^{T}$ is the value of an individual's life used in evaluation safety decisions, as discussed in the introduction.

The term $V^{T}$ represents others' interest

---

[15] In the maximization of

$$\text{(a)}\quad \bar{U}(C,L)=U(C,L)-\lambda(C-(\bar{L}-L)w-W)$$

where $C$ is consumption, $L$ hours of leisure (time not working), $W$ wealth, $\bar{L}$ maximum hours available per time period (e.g., 168 hours per week), and $w$ the wage rate, one first-order condition is

$$\text{(b)}\quad \frac{\partial\bar{U}}{\partial C}=\frac{\partial U}{\partial C}-\lambda=0$$

[16] Equation (14) becomes similar to the equilibrium condition of Fromm when $V^{T}=0$, $u^{iT}=0$, the definitions $\$^{iT}\equiv\partial W^{T}/\partial x^{iT}$ and $p_{iT}^{TT}\equiv\partial p^{TT}/\partial x^{iT}$ are substituted, and (14) becomes:

$$\text{(a)}\quad \frac{\partial W^{T}}{\partial p^{TT}}=\frac{U^{T}}{\partial U^{T}/\partial W^{T}}$$

(One must set the desire for an estate and disutility of the probability of death in Fromm's model equal to zero.) Equation (a) also follows directly from maximizing $V=pU$:

$$\text{(b)}\quad \frac{\partial V}{\partial p}=U+p\frac{\partial U}{\partial W}\frac{\partial W}{\partial p}=0$$

Thus

$$\text{(c)}\quad -\frac{\partial W}{\partial p}=\frac{U}{p(\partial U/\partial W)}=\frac{U}{\partial U/\partial W}$$

where $p\simeq1$. This is the original form in which the problem was solved, including this additional manipulation to be discussed in the text:

$$\text{(d)}\quad -\frac{\partial W}{\partial p}=\frac{U}{\partial U/\partial W}=\frac{CU}{CU'}=\frac{C}{\alpha}$$

$$=\text{value of human life.}$$

in preserving life, while $L^T$ which we label *the value of human life* is the individual's own interest in his safety decision. In this full-information model, however, others' interest in safety is internalized into the individual's decision-making process.

We may now interpret (16). For activities affecting safety for which $u^{iT}>0$, $\$^{iT}>0$, $p_{iT}^{TT}<0$, $L^T>0$, and $V^T>0$, the total cost (or full price) of the activity in equilibrium is comprised of three parts: the monetary cost $\$^{iT}$, the expected loss of the value of human life $-p_{iT}^{TT}L^T$, and the expected loss to others (the insurance company) of net labor income, $-p_{iT}^{TT}V^T$. Of course, $p_{iT}^{TT}$, $V^T$, $\$^{iT}$, and $u^{iT}$ may take on positive and negative values in the real number system, but (16) must hold.

In particular, what values might $L^T$ take on? Since $L^T=U^T/U'^T$, $L^T>0$ since $U^T>0$ by assumption. (See fn. 8.) In general, $L^T>C^T$ holds whenever $\alpha^T<1$, a condition that we expect generally holds for most values of $C^T$ but that as shown below does not necessarily hold for any value of $C^T$. Figure 1a presents the typical case in which a strictly concave lifetime utility function with $U'>0$ will have three regions. Here let $U_B=U^*=0$, where $U^*$ is utility associated with being dead. In the first region $U^T<0$, and thus $\alpha^T<0$ (see Figure 1b). In the second, $U^T>0$ but $\alpha^T>1$ and thus $L^T<C^T$ (see Figure 1c). In the third, which may be called the general case, $0<\alpha^T<1$, and $L^T>C^T$; that is, for a value of expected lifetime consumption above some critical value where $\alpha^T=1$, the value of human life exceeds expected lifetime consumption. This critical value is presumably at a low level of income. However, it is not ever necessary that $\alpha^T<1$ for any $C^T$. In Figure 2, $\alpha^T>1$ for all $C^T>C^0$. In all cases $L^T$ increases more than $C^T$ if income increases since

$$(19)\quad \frac{\partial L^T}{\partial C^T}=\frac{U'U'-UU''}{U'^2}=1+L^TR^T>1$$

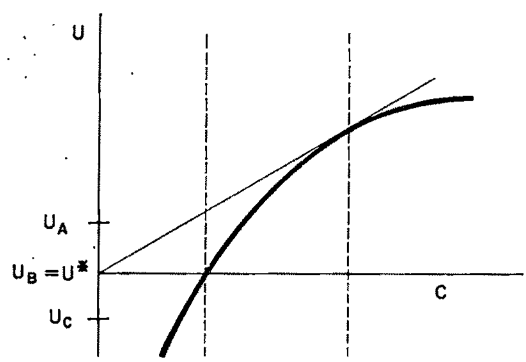

FIGURE 1a

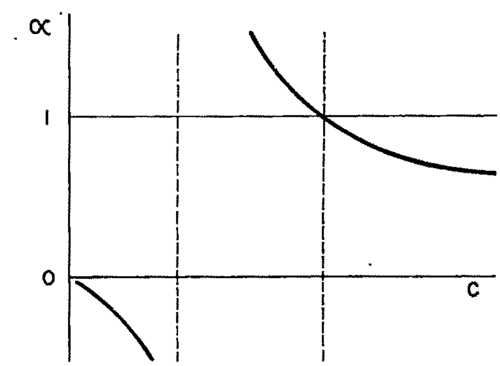

FIGURE 1b

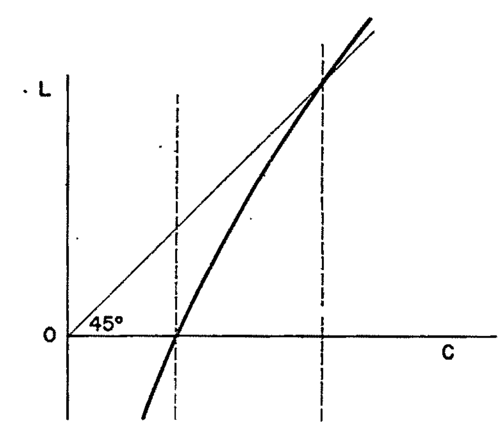

FIGURE 1c

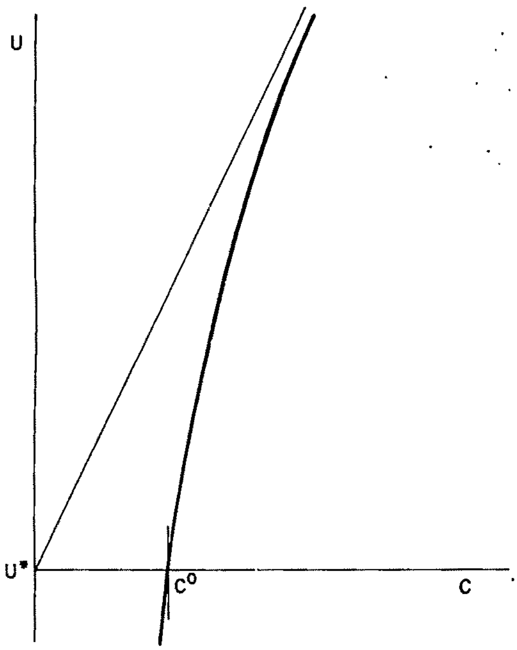

FIGURE 2

where $R^{\mathrm{T}} = -U''/U' > 0$ is the Pratt-Arrow absolute risk-aversion index.

The value of life saving $H^{\mathrm{T}}$ will generally have values close to $L^{\mathrm{T}}$, since their difference $V^{\mathrm{T}}$ will generally be of smaller magnitude than that of $L^{\mathrm{T}}$, except near or in retirement.[17]

The major theoretical conclusion may now be stated. Since the value of life saving $H = L + V = C/\alpha + (Y - C) = C(1/\alpha - 1) + Y$ in the general case where $\alpha < 1$, $H > Y$; that is, the value of life saving is greater than discounted lifetime labor income. Furthermore, in the early and middle years of adulthood when $V > 0$ (due to early dissaving), then the value of life saving in the general case will be greater than discounted lifetime consumption.

Equation (16), in conjunction with (6) and (11), determines lifetime equilibrium conditions. Of the eighty-one combinations of sign values which the vector of variables $[u_{i\mathrm{T}}, \$^{i\mathrm{T}}, p_{i\mathrm{T}}^{\mathrm{TT}}, V^{\mathrm{T}}] \equiv S$ may take on (all may be $+$, 0, or $-$), almost all are of compatible signs. Of these, only a few are of special interest.

When $S = [\pm, -, -, \pm]$, a person is undertaking a risky job, and is compensated with higher pay for the increase in risk.

When $S = [-, +, +, \pm]$, a person is paying for what might be called a "preventive consumption activity," for which his marginal utility is negative; but the activity, such as taking an emetic after an accidental overdose of a drug, considerably increases his probability of life.

Finally, when $S = [0, +, +, \pm]$, a person is spending for a "pure safety activity," in which the only value of the activity is an improved probability of living. This type of expenditure is often relevant for public safety expenditures.

In my earlier paper, I have shown the effects of relaxing some of the assumptions used above. Here I will explore only two of them.

If the utility level associated with death (or of not being alive) is not arbitrarily set at zero, then

$$u(0, 0, \ldots, 0) \equiv u^* \neq 0 \tag{20}$$

In Figure 1a, $U_B = U^*$ and either $U_A$ or $U_C$ instead of $U_B$ may equal zero.

Optimizing

$$V = pU + (1 - p)U^* \tag{21}$$

yields

$$\frac{\partial C}{\partial p} = \frac{U - U^*}{\partial U/\partial C} = L \tag{22}$$

where $p \simeq 1$. Then the numerator of the value-of-life function is the *difference* in utility levels between living and not living. Those who anticipate a pleasant hereafter such that $U$ and $U^*$ do not differ by much therefore will not place a high value on safety expenditures.

[17] For a fuller discussion, see my unpublished paper.

Finally we can incorporate the implications of a person's desire to leave an estate. For convenience, let activity 1 be dollar consumption by others, financed by the person in question. Then $\$^{1t}=1$ and $p_{1t}^{tt}=0$. Thus $u(x, 0, 0, \ldots, 0)\equiv u^*(x^{1t})$ represents one's welfare in death based upon others' consumption. If $X^{1t}$ is the discounted value of such consumption, then $U^*(X^{1t})$ would represent discounted utility of a person who died in period t.

The inclusion of a desire for others' consumption has two implications. First, as more of potential income is allocated for the consumption of others, one's own consumption is necessarily reduced and most likely $L$ will be less (since we cannot arbitrarily restrict the value of $\alpha$, the conclusion must be tentative).

Secondly, a person most likely will increase his lifetime welfare by allocating potential income to others *whether he lives or not.* It would not be unreasonable to assume that whether or not one is alive, one's utility would be increased through others' consumption by about the same degree. Therefore the relationship between $U$ and $U^*$ and the value of $U'$ should be relatively unchanged. If lifetime income and therefore consumption should increase (here at time 0, $C^0=Y^0$), $U$ and $U^*$ both increase, but the former at a faster rate, and $\partial U/\partial C$ declines so that $\partial L/\partial C>1$ and, in the general case, above some level of consumption, $L>C$.

This relationship is shown graphically in Figure 3. The total utility curve at period T is segmented into two parts: 1) utility $\hat{U}$, if those monies planned for others' consumption while alive were not available, and 2) the difference $U-\hat{U}$, which is the increase in utility due to such transfers. At income levels $Y_2$ and $Y_3$, the increase in utility $U_2-\hat{U}_2$ and $U_3-\hat{U}_3$, respectively, due to such transfers is shown to be approximately equal to the utility derived from leaving an estate, $U_2^*$ and $U_3^*$, respectively.

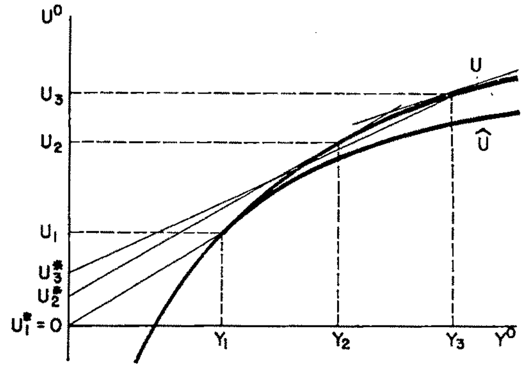

FIGURE 3

At income level $Y_1$, a person allocates nothing for others either while living or in an estate so the graphical presentation is the same as in Figure 1a.

At income levels $Y_2$ and $Y_3$, however, some monies are available for others whether a person lives or not. At $Y_2$, since $Y_2\cdot\partial U/\partial Y=U_2-U_2^*$, the value of human life equals the present value of income, that is, $L=Y=C$. At $Y_3$, the slope of the ray between $U_3$ and $U_3^*$ is greater than that of the tangent to $U$ at $Y_3$. Thus $L_3>C_3$. In general the inclusion of a desire for an estate most likely would not materially change the relationships developed when no desire for any transfers was assumed.

In my earlier paper I extended the basic model to several related aspects. The compensated demand elasticity for safety was found to be unitary, and the uncompensated demand elasticity is bounded by the interval $(-1/2, 0)$. I developed the supply curve[18] and found that safety is a normal noninferior good. Finally, if $\alpha<1$ and if the time $t_c$, when the discounted value of lifetime consumption reaches a maximum, precedes the time $t_y$, when the

[18] Safety is a joint output of household production, and thus the supply curve for safety reflects the increased expenditures necessary to secure greater safety while keeping current utility levels constant.

discounted value of lifetime income reaches a maximum (both for a given income stream), then $L$ and $H$ reach maxima before the discounted value of income reaches a peak, or

$$0 \leq t_L \leq t_H < t_y \tag{23}$$

Therefore the most valuable lives to be saved for a given lifetime income stream are those in their twenty's, early thirty's or possibly younger.

In this section we have determined that all individuals have a value of life $L^T$ which, added to the present value of net income $V^T$, theoretically is used in evaluating activities affecting their probability of living. In general $L^T$ is a multiple of the present value of consumption by the inverse of $\alpha^T < 1$. A heuristic interpretation of $L^T$ is as follows: Consider a person whose $\alpha^T = .2$ and who is considering a prospect involving a 1 percent increase in the probability of living through a period and involving a monetary cost. If he maximizes expected utility and is indifferent between his present circumstances and the prospect, then he must expect 1 percent less welfare due to the monetary cost if he survives the period (for which there is a 1 percent greater chance). Since $\alpha^T = .2$, his lifetime expected consumption upon survival must drop by 5 percent for him to be indifferent to the prospect.

## II. Applications

In this section I consider three broad areas where the model may be applied. The first obvious application is to the demand for safety. Second, applications to demand for other commodities, such as transportation, are explored. Finally implications for measurable utility are drawn.

### *A. Demand for Safety*

The social benefit of a pure safety activity (where $S = [0, +, +, \pm]$) is $p_{iT}^{TT}(L^T + V^T + E^T)$, where $E^T$ is the value of net nonmonetary externalities. At best private benefits equal $p_{iT}^{TT}(L^T + V^T)$. Therefore the private demand for safety will differ from the socially optimal amount depending upon the value of $E^T$.

If government undertakes a pure safety activity, say the $k$th, then the total of social benefits will be

$$B_k^T = \sum_{j=1}^{m} {}^j p_k^{TT} ({}^j L^T + {}^j V^T + {}^j E^T) \tag{24}$$

where $B_k^T$ is social benefits and the index $j$ refers to persons in the affected population. If some individuals do not have an insurance contract as developed in this paper, then ${}^j V^T$ equals the present value of the estate and transfers (including support of family), i.e., net income plus net worth, that one was planning to transfer in the future.

The model suggests that an individual is symmetrical as regards increased or decreased risks. If he accepts $R$ for an increased probability of death $p'$ (where $p' \simeq 0$), then he will pay $R$ for a reduced probability of death $p'$. If individuals are observed to be demanding different amounts, there are other aspects such as transaction costs or anxiety which must be incorporated in the model.

The above analysis holds only for $p_{iT}^{TT}$ sufficiently small such that the marginal conditions are not significantly affected. Equation (16) applies in the small but not in the large. If a person wishes to pay \$5 for a 1/100,000 improvement in the probability of living, it does not follow that he or she will pay \$5,000 for a 1/100 improvement in living, or be willing to receive \$250,000 for taking a one-half chance of losing his or her life. Indeed, in the latter example, many persons could quite rationally not accept any amount of money for the chance.[19] Thus scaling is not linear,

[19] If such is the case, and if people are expected utility maximizers, it would prove that the utility function $U$ is bounded from above.

as Thomas Schelling has proposed.[20]

Finally, the above model does confirm the analysis of James Buchanan and Oi that the doctrine of consumer liability (when the consumer is fully informed) would lead to optimal results, since the efficient full price facing individuals would vary according to their preferences and wealth.

Empirical evidence of the value of human life in various circumstances is sketchy. Schelling conjectures that a statistical life saved may be worth two or three lifetime incomes. Jack Carlson reports values from $200,000 to a million dollars per life saved in *U.S.* defense expenditures and pilot compensation for risky flying. Richard Thaler and Sherwin Rosen estimated the risk premium that 907 individuals demanded for dangerous jobs; they found a resulting value of human life of around $200,000, which is several times lifetime earnings. Thus what evidence is available tends to confirm the major theoretical finding of this paper, that the value of life is greater than discounted earnings.

### *B. Demand Studies*

Since a change in safety is one factor in the cost (or benefit) of an activity, such a change will have predictable effects upon demand. Specifically, if $\eta^{i\mathrm{T}}$ is full price elasticity of a commodity ($u_{i\mathrm{T}}>0$), where the full price $= s^{i\mathrm{T}} =$ denominator of (16), then the "probability-of-living" elasticity of demand for good $i$, $\epsilon^{i\mathrm{T}}$, is

$$(25)\quad \epsilon^{i\mathrm{T}} = \frac{\partial x^{i\mathrm{T}}}{\partial p_{i\mathrm{T}}^{\mathrm{TT}}}\frac{p_{i\mathrm{T}}^{\mathrm{TT}}}{x^{i\mathrm{T}}} = \frac{\partial s^{i\mathrm{T}}}{\partial p_{i\mathrm{T}}^{\mathrm{TT}}}\frac{\partial x^{i\mathrm{T}}}{\partial s^{i\mathrm{T}}}\frac{s^{i\mathrm{T}}}{x^{i\mathrm{T}}}\frac{p_{i\mathrm{T}}^{\mathrm{TT}}}{s^{i\mathrm{T}}}$$

$$= \frac{p_{i\mathrm{T}}^{\mathrm{TT}}\cdot H^{\mathrm{T}}}{s^{i\mathrm{T}}}\cdot \eta^{i\mathrm{T}}$$

and therefore $\epsilon^{i\mathrm{T}}$ equals $\eta^{i\mathrm{T}}$ times the percentage of the full price of the $i$th commodity attributable to the value of life saving, namely $p_{i\mathrm{T}}^{\mathrm{TT}}H^{\mathrm{T}}/s^{i\mathrm{T}}$. This formula is identical to that of the price elasticity of demand for an input where the elasticity of substitution between the input and all other inputs in a production function is zero. Where $u_{i\mathrm{T}}>0$ and $p_{i\mathrm{T}}^{\mathrm{TT}}>0$, an improvement in the safety of a product *must* increase the demand for it, contrary to Oi's result that for some goods an improvement in quality may decrease market demand.[21]

Including a safety variable can improve the econometric estimation of demand for goods, such as for many sectors of transportation involving a safety aspect. The improvement in safety may predict part of the unexplained increased in demand for, as an example, commercial air transportation.

### *C. Measurement of Utility*

Previous attempts at measuring utility have been unsuccessful. However, if data relevant to safety decisions were available, they would help us measure the shape of such a function, if the assumptions of this model are appropriate. If independent measurements of $p_{i\mathrm{T}}^{\mathrm{TT}}$, $\$^{i\mathrm{T}}$, $C^{\mathrm{T}}$, and $V^{\mathrm{T}}$ can be made for pure safety activities, $L^{\mathrm{T}}$ and therefore $\alpha$ may be estimated for a wide range of incomes.

Suppose that empirical data generated average values of human life at a given age

[20] See p. 152–54. Also see Martin Bailey, p. 164, regarding scaling.

[21] Oi's model was for the demand for market goods, a percentage of which were defective and inflicted a known money cost. Market demand would have positive elasticity to changes in risk when (p. 11)

$$\text{(a)}\qquad -\eta_p < \frac{1}{1+\dfrac{W}{P}}$$

where $\eta_p$ is the market price elasticity for risky activities, $P$ is market price, and $W$ is net damage cost per defective unit. In our model $W=H^{\mathrm{T}}$, which in the general case makes the right-hand side of (a) imperceptably greater than zero. Therefore demand for any good is negatively related to its risk.

TABLE 1—PRESENT VALUE OF CONSUMPTION AND VALUE OF HUMAN LIFE (HYPOTHETICAL)

| Consumption | \$30,000 | \$70,000 | \$100,000 | \$200,000 |
|---|---|---|---|---|
| $L$ | \$10,000 | \$70,000 | \$150,000 | \$400,000 |
| $\alpha$ | 3 | 1 | 2/3 | 1/2 |

as hypothesized in Table 1. If people are expected utility maximizers, then the general shape of the total utility curve may be derived from such data.

Other general applications of the model are possible, such as to optimal population theory, where the objective may be to maximize discounted utilities. The model in general therefore continues the modification of classical consumer theory to broaden and modify the simplistic Hicks-Allen representation of consumer optimization.

# The Demand for High-Powered Money

*By* JAMES R. LOTHIAN*

The resurgence of the quantity theory in the past two decades has brought with it a renewal of an often-debated question—how to define money. Though the answers that have been given vary widely, most economists, with little hesitation, would probably settle on a monetary total similar to $M_1$ or $M_2$ in the United States as "the" definition of money.

What this paper shows, however, is that the choice is not nearly so simple. Empirical analysis is often circumscribed by lack of data on many of the variables theory suggests can affect the demand for money, such as the interest rates paid on various categories of deposits and the quality or "moneyness" of those deposits. Under some circumstances the omission of these variables can have a serious effect on the stability of conventional deposit-inclusive definitions of money, causing them to be highly imperfect indicators of the effects of money on the overall economy.

The solution that I propose in these situations is to return to a narrower definition of money, high-powered money alone. The rationale is that since high-powered money is of relatively constant quality over time and space, such specification errors are likely to be less important for high-powered money than for deposit-inclusive totals. The demand for high-powered money should be more stable than the demand for other monetary aggregates.

Since differences in deposit quality and deposit interest rates are likely to be particularly great across countries, I test this proposition by analyzing the demand functions for high-powered money and for various other monetary assets estimated across an international time-section sample spanning forty countries in the postwar period. On the whole the results support my hypothesis. I find that high-powered money is unambiguously the most stable total across the countries in my sample, even when it is judged on the basis of the constant velocity model and the other totals are judged on the basis of a more sophisticated model of money demand. Moreover, I find evidence of several sorts that the factors which a priori could be expected to produce this result have actually been operable.

## I. Theoretical Considerations

### A. *Money Demand Functions*

To be able to make a judgment about which monetary total is most stable in demand, and hence which is the most useful definition of money, we first have to decide which variables we will assume to be the most important determinants of demand and which we will assume to have only a negligible impact and will ignore in the statistical analysis.[1] In discussing the

* Economist, First National City Bank. In preparing this paper and the dissertation upon which it is based, I have benefitted from the comments and assistance of a large number of people. I am particularly indebted to Milton Friedman for key suggestions in the dissertation stage of my work and to Arthur Gandolfi for valuable discussions of various drafts of this paper. I also want to thank W. H. Bruce Brittain, Phillip Cagan, Robert J. Gordon, Wallace Huffman, Dudley D. Johnson, James P. Smith, Richard Zecher, and the managing editor of this *Review*.

[1] Milton Friedman and Anna Schwartz (1970) provide a strong statement of the position that choosing a definition of money is primarily an empirical issue. They argue further that stability in demand is an appropriate criterion for deciding between alternative definitions of money. A related criterion for defining money has been advocated by V. Karuppan Chetty, who has attempted to estimate directly the substitution relationships between various monetary totals.

factors affecting the stability of high-powered money relative to deposit-inclusive definitions of money and in the subsequent statistical analysis, I assume a simple and widely used money demand function that is derivable from the modern quantity theory and has the form:

$$(1) \qquad m = f(y_p, r)$$

where $m$ is the desired ratio of money to income, $y_p$ is permanent real income, and $r$ is "the" nominal rate of interest.

As a first approximation for statistical purposes, I also use a more restrictive formulation based upon the constant velocity model of the earlier quantity theory,

$$(2) \qquad m = k$$

where $k$—the Cambridge $k$—is a constant.

Before we actually use these demand functions to evaluate competing definitions of money empirically, I want to discuss in detail some of the other omitted influences on money demand and their likely effects on the various monetary totals. But first, let us briefly outline a more general approach to the demand for money that relaxes some of the restrictive assumptions implicit in equation (1).

A model of money demand like Benjamine Klein's (1970, 1974), which is similar to the formulations used by Edgar Feige (1964) and by Morris Perlman and is in the spirit of the new approaches to consumer theory developed by Gary Becker and Kelvin Lancaster (1966, 1971), is a particularly useful starting point. In his model Klein makes explicit the distinction between the services individuals receive from money and the real stock of money that they hold, and he assumes that the services are what provide utility to money holders. Then by specifying an individual's demand and production functions for monetary services he derives an individual's (stock) demand function for money that we can express as

$$(3) \qquad m = g(y_p, P_M, \beta_M)$$

where $P_M$ is the price of the monetary services from the marginal unit of money, equal to the difference between $r$ and the rate of interest paid on money $r_M$, and $\beta$ is an index of the quality of money, a term from the individual's production function for monetary services.[2]

### B. *Conventional Definitions of Money*

The estimation of an equation based on (1) rather than on the more complete formulation (3) can lead to several types of specification error when money is defined conventionally to include deposits.[3] Let us consider the effect of omitting $r_M$ first.

Since $r_M$ is likely to move together with the overall level of interest rates, the coefficient in the auxiliary regression of $r_M$ on $r$ will be positive, which means that the coefficient of $r$ in the regression based on (1) will be biased downwards in absolute value. But if the correlation between $r$ and $r_M$ is high, this type of specification error may have only a small effect on the stability of the demand for conventionally defined money.

Both across countries and within some countries over time this is unlikely to be the case. With no interest paid on currency, $r_M$ will be equal to the product of $r_D$, the rate paid on deposits, and $D/M$, the ratio of deposits to money. If the interest rate paid on deposits is competitive (in the sense of reflecting a zero marginal profit), it in turn will equal $r_I(1-R/D)$,

[2] Equation (3) is derivable from a demand function for monetary services of the form $S^d = D(R, y_p)$ and from a production function for monetary services of the form $S = \beta_M(M/P)$, where $S$ represents monetary services; $M/P$ is the real stock of money; $\beta_M$ is a variable coefficient of production; $R$ is the rental price of a unit of monetary services, equal to $P_M/\beta_M$; and the superscript $d$ signifies quantity demanded.

[3] See Henri Theil, pp. 504–56, for a discussion of specification analysis. Note that to simplify the discussion throughout, I am only considering one alternative definition of money, the sum of currency and total commercial bank deposits.

where $r_I$ is the interest earned on bank assets and $R/D$ is the ratio of bank reserves to deposits.[4] Hence, even if movements in $r$ and $r_I$ are closely related, differences in $R/D$ due to differences in reserve requirements or in other factors affecting banks' preferences for reserves relative to deposits will be reflected in differences in $r_D$. The existence of ceilings on either $r_I$ or directly on $r_D$, which cannot be evaded costlessly, will also reduce the correlation of $r$ and $r_M$.

What may be an even more serious problem empirically than unaccounted differences in own interest rates on money are differences in the quality of money. These differences can stem from differences in the degree of financial development of different countries or from the method used by banks to circumvent regulatory constraints on the interest they pay on deposits and earn on their assets. This second source of problems would be relevant both across countries that have differing regulations and within countries having high and variable rates of inflation along with regulations.

We can categorize these quality differences under a number of headings, each of which has slightly different implications. One assumption is that quality differences, or differences in the services offered in connection with money, are exactly equivalent to implicit interest payments on deposits. In this case their omission produces the same results as omission of explicit interest payments.

Another assumption is that quality differences are of a factor-augmenting form, involving differences in the $\beta_m$ of equation (3). In this case their impact is more difficult to assess, since an increase in $\beta_M$ has both a negative production and a positive price effect on the derived demand for money, with the net outcome ambiguous. If the net effect is positive this type of quality difference will cause a downward bias in the income coefficient in regression counterparts of (1), since countries that are more financially sophisticated are also likely to be on the whole more developed. It may also cause a downward bias (in absolute value) in the interest rate coefficient if deposit rate ceilings are the rule, since in countries with high rates of inflation banks will make more attempts to circumvent regulations.

When circumvention of interest ceilings provides the impetus, another form of what we have termed "quality changes" may take place. Banks may introduce a new liability that is unregulated as a substitute for the regulated deposits. In some instances, such as with Eurodollar deposits at foreign branches of American banks, these new liabilities may be close substitutes with existing deposits and, in principle, simply could be added to these totals to preserve their homogeneity. In actuality, however, this is unlikely to be an option, since the success of introducing new unregulated liabilities as substitutes for existing deposits depends upon their going unnoticed by the authorities. Hence, to the extent that this is the method of circumvention, the interest coefficient will be biased upwards in absolute value. Countries with high rates of inflation will have recorded deposit totals that are lower than the true totals that include the new goods.

A fourth and perhaps most realistic assumption is that quality differences affect not only the monetary service stream received from deposits, but also their substitutability with other assets. That is, we can view deposits as supplying more than one type of service, bond-type services in addition to monetary services. Some types of regulations and some patterns of finan-

[4] This formulation is discussed in Klein (1970, 1974). As he points out, even where entry into banking is regulated, competitive interest rates could still exist if competition is allowed in the provision of nonprice services which are viewed by individuals as equivalent to explicit interest payments.

cial development may lead to a change in the mix of these services. For instance, to circumvent ceilings on deposit rates, banks may offer relatively more bond-type services in connection with deposits, thus increasing their substitutability with bonds and decreasing their substitutability with currency. The end result would be to decrease the stability of the demand for money defined to include deposits.

### C. *High-Powered Money*

All of these factors—changes in own interest rates and the various types of quality changes—have direct effects on deposits but not on currency held by the public, making currency a potentially attractive alternative to broader definitions of money.[5] However, if we use currency alone as the definition of money rather than, say, the sum of currency and total commercial bank deposits or $M_2$, a consistent accounting practice would be to redefine the currency component of $M_2$ to include all of high-powered money.[6]

The use of high-powered money as the definition of money can also be viewed from a different perspective. When no interest is paid on either the deposits of commercial banks with the monetary authorities or on currency and hence on vault cash, reserve holdings of commercial banks set an upper limit on the extent to which interest can be paid on deposits. Reserves are in effect the portion of deposits which always yield only monetary services and no interest. The remainder of deposits, equal to the difference between deposits and reserves, is the portion of deposits which, at least potentially, yields interest. A holder of deposits is thus a participant in a tie-in sale, receiving these two components of deposits. The similarities in service flows between the reserve portion of deposits and currency held by the nonbank public and between the excess of deposits over reserves and other interest-bearing assets, such as bonds, may mean that the reserve portion of deposits is a close substitute with currency held by the nonbank public, while the remainder of deposits is a close substitute for the other interest-bearing assets.[7]

The analogy between this approach and Lancaster's is readily perceivable. In the simple case with which we are dealing, we can distinguish three assets and two characteristics: the former are currency, deposits, and bonds; the latter are moneyness (common to currency and deposits) and bondness (common to bonds and deposits). In this formulation, Lancaster's model explains several phenomena relevant to our discussion. In particular, it provides a rationalization for the proposition that changes in the mix of characteristics of deposits towards relatively more bondness make deposits and bonds closer substitutes, since in Lancaster's model "... closeness of substitution [is] an intrinsic effect, depending on objective characteristics of goods ..." (1967, p. 67). Hence it explains why such changes will increase the stability of high-powered money relative to money defined to include deposits. As we approach the polar case in which the only part of deposits that yield monetary services is the high-powered money por-

[5] See Friedman and Schwartz (1970, pp. 142–46), for a similar argument.

[6] When deposits of commercial banks are included in the definition of money, vault cash of commercial banks and other high-powered money reserves of commercial banks are excluded to avoid double-counting. However, if commercial bank deposits were excluded a consistent procedure would be to redefine currency held by the public to include the total monetary liabilities of the monetary authorities, or high-powered money. One way to view this is that the public is now expanded to include commercial banks just as the public can be considered to include nonbank financial intermediaries when money is defined as the total of currency and commercial bank deposits.

[7] While this may not hold as a general proposition it will be more nearly the case when variations in deposit quality affect the meaning of deposits to holders, as I explain below using Lancaster's framework.

tion, progressively smaller increases in the cost of holding deposits will lead to progressively larger decreases in deposit holdings. And in the polar case itself, deposits will be a linear combination of the characteristics of the other two goods and any increase in the cost of holding deposits will cause them to be technologically inefficient (in consumption) and hence cease to exist.[8]

## II. Empirical Results

### A. *The Data and Empirical Model*

To compare the stability of the demand for high-powered money with that of other monetary totals across countries, I have used analysis of variance techniques and their multiple regression analogues. The data used span 40 countries over the period 1952 to 1966. For each country, I have fifteen yearly observations for real per capita net national product (in 1958 dollars), for the rate of increase of the cost of living index, and for four monetary totals: high-powered money, currency held by the public, deposits, and the sum of currency and deposits, which I refer to as $M_4$ throughout. Deposits are defined broadly to include all private deposits at bank-type financial intermediaries, and high-powered money is defined as the total monetary liabilities of the monetary authorities. It therefore includes total currency outstanding along with bank and, where they exist, other private deposits at the central bank. For 22 of the countries I also have yearly figures for long-term bond yields.[9] Separate analysis is carried out for this 22-country sub-sample.

The regressions are based on the two simple general demand functions presented above and take the following form in the covariance analyses:

$$\text{(4)} \quad \log(M/Y)_{it} = \alpha_i + \delta_t + \beta_1 \log(y/L)_{it} + \beta_2 r_{it} + \epsilon_{it}$$

where $i$ denotes the country, t denotes the time period, $M/Y$ is the number of weeks of income held as the particular asset, $y$ is real income, $L$ is population, $r$ is the rate of interest, $\alpha_i$, $\delta_t$, $\beta_1$, and $\beta_2$ are parameters to be estimated, and $\epsilon_{it}$ is the error term assumed spherical normal.[10] This formulation assumes that: (a) actual and desired money balances are equal; (b) the demand function is homogeneous of degree one in population and of degree zero in prices; (c) the income elasticity is constant; (d) the semilogarithmic interest rate slope term is constant; and (e) measured income is a close approximation for permanent income. The first four assumptions are standard in much money demand analysis. The last assumption is an empirical expedient that may be imperfect within countries over time but appears reasonable

[8] In this case (which is the case of the tie-in sale) the demand for high-powered money will be unaffected by individual's choices of deposits versus currency and will depend only on their choice of characteristics. This becomes less true as deposits become more efficient, that is, as the production possibilities curve becomes more concave.

[9] The income total for almost all countries was net national product in current prices, taken from the United Nations' (*U.N.*) *Yearbook of National Account Statistics, 1969*. Publications of the *U.N.* principally issues of the *Demographic Yearbook*, provided midyear estimates of population. The bulk of the data for the four monetary totals, the data on interest rates, and the cost of living indices (1958 = 100), used to convert the income figures to constant prices and to compute yearly rates of change of prices, came from the 1966–67 and 1967–68 supplements to the International Monetary Fund's (*IMF*) *International Financial Statistics*, together with various monthly issues of that publication. Exchange rates for 1958, adjusted for changes in purchasing power parity and used to convert real per capita income to dollars, came from the *U.N. Yearbook of National Account Statistics, 1963*, Table 3B. I initially used only a broad definition of deposits because of difficulties in constructing a series for demand deposits at commercial banks, the most important of which was that for some years for some countries separate demand deposit data were not available from the *IMF*. As reported in the conclusion, later work with a demand deposit series obtained in part from other sources alters none of my results.

[10] The corresponding regression for an analysis of variance imposes the constraint that $\beta_1 = \beta_2 = 0$.

[a] The International Monetary Fund (*IMF*) was the main source of monetary data and the United Nations (*U.N.*) the main source of income data.

[b] High-powered money, currency, broadly defined deposits, and the sum of currency and broadly defined deposits are represented by $H$, $C$, $D$, and $M_4$, respectively, and nominal income by $Y$.

across countries, where differences in transitory income seem to be a relatively small proportion of differences in measured income. The next to last assumption, unlike the logarithmic formulation that is also sometimes used, implies a finite demand for money at a zero rate of interest, and is justifiable if there are some increasing marginal costs of holding money.

### B. *Stability of Alternative Totals*

Analyses of variance and of covariance of the monetary totals are presented in Table 1 to provide evidence on the relative stability of each of the four totals over time and across countries under both specifications of the demand for money function. The mean squares for countries and years of the analyses of variance are measures of the absolute variation in the fraction of income held in the form of each asset ( or in velocity) across countries and over time, while those in the analyses of covariance are measures of the variations in asset holdings across countries and over time after allowance is made for the effects of the independent variables, real per capita income in the full sample, and both real per capita income and the rate of interest in the subsample. Tests of significance of these mean squares are therefore tests for significant departures from the respective models of the demand for money.[11]

[11] The mean square for countries is the regression sum of squares due to the dummy variables used to allow the $\alpha_i$ to differ, the mean square for years is the regression sum of squares due to the dummy variables used to allow the $\delta_t$ to differ, and the remainder sum of squares is the sum of squared errors from the regression. A test of the null hypothesis that the $\alpha_i$ are all equal is a test

The results of both types of analyses strongly support the view that narrower totals in general and high-powered money in particular are more homogeneous across countries. In the analyses of variance for the full sample, the country mean square for high-powered money is less than two-thirds that of currency and less than one-third of the other two assets. In the subsample, it is at the most one-half of the mean square of the other three assets. In the analyses of covariance, high-powered money, too, is the least variable across countries in both samples. What is particularly surprising when these results and the analyses of variance results are compared is the minute reductions in the mean square for high-powered money across countries (1.36 to 1.24 in the full sample and .80 to .76 in the subsample) and the lower unadjusted mean square for high-powered money than the adjusted mean squares for either deposits or $M_4$ (1.36 versus 3.01 and 2.24 in the full sample and .80 versus 1.18 and .88 in the subsample).

Over time the results are more mixed, and appear somewhat different from those obtained across countries. In the analyses of variance, high-powered money proves least variable in the full sample and $M_4$ in the small sample, while in the analyses of covariance, currency and $M_4$ prove equally less variable in the full sample and currency proves least variable in the small sample. However, in both sets of covariance analyses, with the exception of deposits in the full sample, these mean squares for years are insignificant at the .05 level.[12]

for no significant variation across countries; a test of the null hypothesis that the $\delta_j$ are all equal is a test for no significant variation over time. Rejection of the alternative hypotheses that in each instance they are unequal implies that velocity can be taken as constant and equal to its geometric mean.

[12] All of the mean squares in the analyses of variance, with the exception of the mean square for years for high-powered in the full sample (which is barely significant at .05), are highly significant. Those for countries in the analyses of covariance remain so.

## C. *Estimated Demand Functions*

Summary statistics and coefficients of the independent variables for the regressions underlying the covariance analysis—pooled regressions with individual intercepts for countries and years—together with the results of five other types of regressions are presented in Tables 2 and 3. These results permit comparison with the findings of other demand for money studies and also help illuminate the differences between the cross-country and within-country stabilities of different totals.

The implied income elasticities and the interest rate coefficients are for the most part highly significant and agree closely with estimates obtained in previous money demand studies.[13] The pooled regressions with single intercepts, the pooled regressions with individual yearly intercepts, and the country-mean regressions, all capture primarily cross-country relationships.[14] In these regressions the income elasticities of demand for real balances range from close to 1.0 for currency to close to 1.5 for deposits. The interest elasticities (evaluated at the mean of the interest rate, .054) all indicate an inelastic response of asset holdings to changes in interest rates and range from less than $-.10$ for high-powered money to a little over $-.40$ for money.

[13] For example, see the time-series studies by Klein, Allan Meltzer, Friedman and Schwartz (forthcoming), A. A. Walters, and the cross-state studies by Feige and Arthur Gandolfi. Note that my estimates of income elasticities (of real cash balances held in the form of each asset) equal one plus the income coefficient. Hence an income coefficient significantly different from minus one implies an income elasticity significantly different from zero. Correspondingly, a coefficient of determination close to zero implies no additional gain in explanatory power from relaxing the assumption of unit income elasticity (or from including interest rates).

[14] Both the yearly intercepts and the averaging inherent in the country-mean regressions dictate this. The primarily cross-country nature of the regressions with single intercepts is peculiar to these data. Such regressions treat within-country and cross-country variation the same, and the latter is a predominant portion of the total variation in holdings.

[a] The *IMF* was the main source of monetary and price data and the *U.N.* of income and exchange rate data.
[b] Real per capita income in 1958 dollars is represented by $y/L$ and the average rate of change of the cost of living index by $g_p$. Standard errors of the coefficients are beneath them in parentheses.

The pooled regressions with individual country constants and the pooled regressions with individual yearly and country constants both seem to capture primarily time-series relations. They yield estimated elasticities fairly similar to those from the three types of cross-country regressions. The only substantial differences are in the interest elasticities of deposits and money and the income elasticities of high-powered money and currency, all of which are lower in the pooled regressions with individual country constants than in the cross-country regressions.

The standard errors of these regressions provide information similar to though not fully independent of the results of the covariance analyses. Again, high-powered money is the most stable total across countries. Within countries currency appears somewhat more stable than alternative totals, though again the differences among them are slight.

A problem with the within-country comparisons, however, is that for none of the assets are the individual within-country regressions statistically homogeneous.[15] The implication is that from the standpoint of the time-series relations there are

[15] The $F$-ratio to test jointly the homogeneity of both slopes and intercepts in the regressions for the individual countries, showed significant differences at less than the .001 level for all assets in both samples. Tests of individual yearly regressions revealed the opposite—no significant differences at the .10 level.

[a] The *IMF* was the main source of monetary, price, and interest rate data and the *U.N.* of income and exchange rate data.

[b] Real per capita income in 1958 dollars is represented by $y/L$ and the rate of interest by $r$. Standard errors of the coefficients are beneath them in parentheses.

some important omitted variables that differ in their impact from one country to the next. An alternative way of dealing with the time-series relations therefore may be in order. One solution is to use an error component model, such as that proposed by Pietro Balestra and Marc Nerlove, which views the error term in the model as being made up of two parts: a cross-country error and a remainder. When this technique is used we get another set of time-series estimates which are also presented in Tables 2 and 3. What they show is, as in the cross-section regressions, the clear superiority of high-powered money. In both samples the standard errors of estimate for the regressions for high-powered are lower than those for the regressions for the other assets.

One reason for the differences between the relative stabilities of different totals across countries and within countries uncovered in some of the regressions is brought out by examination of the interest rate coefficients. In the regressions in which high-powered money is most stable, its sensitivity to interest rates is much lower than that of deposits and $M_4$. This is precisely what one would expect if there were specification bias in the deposit and

money regressions, caused by either the existence of close substitutes for deposits introduced to circumvent interest rate ceilings, or by a greater degree of substitutability of deposits for bonds than of the high-powered money portion of deposits for bonds.

What may be more important sources of differences between the two sets of results are differences between cross-country and within-country variations in deposit quality. One might plausibly expect the former to be considerably greater since differences in the degree of financial development across countries are probably much greater than those that are likely to exist within countries over the relatively short time span covered by the sample. Omitting this variable, therefore, would decrease the stability of $M_4$ relative to narrower totals across countries and have little effect within countries.

This second explanation, moreover, is given credence by several additional types of evidence. In the analyses of variance and of covariance, variations in holdings of deposits and of $M_4$, both absolutely and relative to high-powered money, were much lower in the small sample that is the more homogeneous of the two with respect to degree of financial development. Regressions run with country means and incorporating the ratio of banking offices to population as an index of deposit quality also support this hypothesis.[16] Hence, differing degrees of financial sophistication seem to account for at least part of the difference between the performance of $M_4$ and high-powered money across countries and, therefore, may also account for part of the differences between the cross-country and the time-series results.

## III. Summary and Conclusions

The central theoretical proposition of this paper is that substantial variations in the cost of holding deposits relative to the costs of holding currency and other assets and in the quality or "moneyness" of deposits, such as exist across countries and within some countries having high and varying rates of inflation and ceilings on deposit rates, will substantially reduce the stability of the demand for money defined conventionally to include deposits while having only a minor effect on the stability of the demand for money defined more narrowly as high-powered money alone. In these circumstances high-powered money may therefore be a more useful definition of money than deposit-inclusive monetary totals.

The empirical evidence I have presented in the main supports this proposition. I have found that across countries high-powered money is the most stable of the four totals I have examined even when it is judged on the basis of the simple constant

[16] The data and their sources are described in my dissertation. The regression for the country means of deposits for 34 countries in the full sample for which data were available was

$$\log (D/Y) = .413 + \underset{(.093)}{.345} \log (y/L) + \underset{(563.3)}{1637.8} B/L - \underset{(.776)}{1.260} g_p$$

$R^2 = .74$; $SE = .382$

and for the 22 countries in the small sample was

$$\log (D/Y) = .484 + \underset{(.076)}{.425} \log (y/L) + \underset{(492.7)}{945.0} B/L - \underset{(3.347)}{9.174} r$$

$R^2 = .85$; $SE = .274$

where $B/L$ is the deposit quality variable and where standard errors are beneath the coefficients in parentheses. Higher income coefficients were obtained in similar regressions that omitted $B/L$ (.528 and .524, respectively), which is what one would expect if an increase in deposit quality caused by increased financial development has a positive effect on the demand for deposits and if more financially developed economies are also more developed on the whole. In the above regressions $B/L$ was significant in both instances at the .05 level which it never was when I used high-powered money as the dependent variable.

velocity model and the other totals are judged on the basis of a more sophisticated model of money demand. Moreover, this greater stability of high-powered money appears directly attributable to the factors which theory suggests will have an important destabilizing influence on the demand for deposits. Specification analysis of various types of regressions, the observed differences in the stability of $M_4$ relative to high-powered money in the two samples, and the results of regressions which use a proxy for the quality of deposits as an independent variable all tend to confirm the importance of variations in deposit quality. The one major piece of evidence which does not support the hypothesis is that high-powered money is if anything less stable than either currency or $M_4$ within countries. But as already mentioned, this finding is consistent with the other evidence if, as appears reasonable, variations in deposit quality are on average of only minor importance within countries.

Moreover, this greater cross-country stability of narrower totals in general and high-powered money in particular is not just a statistical quirk peculiar to these data. Analysis of other studies indicates that this result still holds when other assets, specifically $M_1$ and its deposit component, are considered and other samples are used.[17] As an additional check, I compiled an $M_1$ series for my group of countries. The regressions I ran for both the 40 countries and the 22 countries also indicate that high-powered money is more stable than either $M_1$ or the deposit component of $M_1$.[18]

My findings also provide evidence of several sorts bearing on the overall stability of money demand. They show that given the variations in factors which could plausibly be expected to affect the demand for money across countries, it is reasonably stable. Estimates of international variations in money holdings are not radically greater than the intranational estimates.[19] In addition, even though these international variations are both significant and substantial, it is clear that even so simple an hypothesis as constant velocity has considerable merit. For example, from knowledge of high-powered money and of its average velocity, one can account for an overwhelming proportion of the variance in the level of nominal income or in its rate of change— over 95 percent of the variance of the level in 1958 and over 90 percent of the variance of its average annual rate of change. In addition, my estimates of money demand functions on the whole accord fairly well with esti-

[17] Estimates of coefficients of variation of velocity derived from regressions similar to mine contained in studies by Hannan Ezekial and Joseph Adekunle, by Morris Perlman, and by Henry Wallich show that currency is more stable than broader totals (either $M_4$ or both $M_1$ and $M_4$, depending upon the study) and that holdings of both broader totals are more variable than high-powered money is in my full sample. Additional comparisons which I have made with an extended and otherwise revised version of Perlman's data and which I report in my dissertation show high-powered money to be the most stable total.

[18] The regression for the country means of $M_1$ holdings for the 40-country sample was

$$log\ (M_1/Y) = .840 + \underset{(.056)}{.259}\ log\ (y/L) - \underset{(.411)}{.276}g_p$$

$R^2 = .39; \quad SE = .345$

and for the 22-country sample was

$$log\ (M_1/Y) = 1.337 + \underset{(.056)}{.233}\ log\ (y/L) - \underset{(3.338)}{3.912}r$$

$R^2 = .50; \quad SE = .278$

where standard errors of the coefficients are beneath them in parentheses. We can compare the standard errors of estimate of these regressions of .345 and .278 with the standard errors of estimate for similar regressions for high-powered money of .295 and .236, respectively.

[19] Friedman and Schwartz (forthcoming) report coefficients of variation of the levels of velocity of $M_2$ in the United States of .32, and in the United Kingdom of .18 over the years 1880–1968. Estimates for the velocity of total adjusted commercial bank deposits from cross-state data, made available by Gandolfi, range from .17 in 1929 to .20 in 1933.

mates others have obtained from long-term studies of the United States and the United Kingdom and from cross-section studies of the United States.[20] Given the substantial independence of my data from theirs, this close agreement of results provides a strong corroboration of their results. Conversely, it casts considerable doubt on estimates from postwar time-series for those two countries which in general conflict greatly with both long-term time-series and cross-section estimates.[21]

An obvious implication of my findings is that for international studies in which the stability of the demand for money is a key assumption, such as in monetarist models of the balance of payments or of exchange rates, the use of high-powered money as the definition of money may prove extremely fruitful. In studies of that type it also has the added advantage of eliminating the need for separate relationships to explain the conventional money multiplier and conventional money demand. For countries having no income data or data of dubious accuracy there are also direct applications for these findings. By extension they also may prove useful in time-series studies of economic conditions in countries experiencing rapid inflation or substantial changes in their financial structure.

My results also have implications for monetary policy. Since inflation coupled with regulation of banking tends to reduce the homogeneity of deposits, conventional definitions of money may become highly imperfect indicators for monetary policy in such situations. On the one hand, my findings suggest that policy should be such that supply and demand are not made more interdependent. And on the other, they suggest that, having made them so, the monetary authorities should look for a more homogeneous total as an indicator and not deduce from the instability in demand of a nonhomogeneous total that monetary aggregates play only a weak role in the economy.[22]

Perhaps the most interesting implications of these results are for the definition of money. Most of the current debate over how to define money has centered upon whether to include various types of time and savings deposits in the definition of money. My results suggest that the focus of current debate has been too narrow, that the range of plausible alternative definitions of money and the factors influencing the selection of one of these alternatives are both broader than is commonly realized. They indicate that an earlier definition of money as high-powered money alone may be a useful alternative to these conventional definitions of money. And because the differences in the performance of high-powered money and deposit-inclusive definitions of money across countries can be attributed to variations in deposit quality, these results also indicate the importance of asset quality in deciding upon a definition of money.

[20] In addition to the studies cited in fnn. 13 and 17, see the cross-country study by James Hanson and Robert Vogel.

[21] Estimates of income elasticities obtained from the studies referred to in the previous footnote tend to fall in the range of 1.0 to 1.3. Estimates obtained with postwar data (see Stephen Goldfeld) are usually considerably below 1.0.

[22] The United Kingdom currently provides an instructive example. Changes in the regulations surrounding banking appear to be a major cause of the marked divergences over the past several years in the growth rates of the two published deposit-inclusive definitions of money. These changes have undoubtedly decreased the homogeneity of both totals and thus have drastically increased the difficulties in assessing British policy.

# Benefit Shares and Majority Voting

*By* ARTHUR T. DENZAU AND ROBERT J. MACKAY*

In the burgeoning literature on collective decision making, attention generally has been focused on the public provision of goods in equal quantities to all recipients. As a result, there has been little positive analysis of the effects of differential distribution of the benefits of public activities. This state of affairs contrasts with the more developed literature on the effects of differential distribution of the costs of public activities. By analogy to the tax share concept in the study of cost sharing, this paper examines the effects of differential benefit shares, or of changing benefit shares, on voting behavior at the individual and aggregate level in a majority voting model.

Just as the early literature on cost sharing often assumed equal sharing by all and thus the same tax share for all, the assumption of equal quantities for all can be interpreted as equal benefit shares. This equal quantities assumption requires a distinction between production units (the units relevant for production and cost functions) and consumption units (the units relevant for individual preference relations).[1] This distinction immediately raises the issue of the distribution of public benefits, i.e., the transformation of production units into consumption units. A benefit share measures the rate at which a production unit is transformed into an individual's consumption units.[2] For example, in the case of a "pure public good," without exclusion, the benefit shares would all equal unity.

The problem this paper is concerned with can now be stated in its simplest form by the following example. Suppose that the state has made private trading in bread illegal. In lieu of market exchange, the government distributes the bread at a zero price, with the cost of the bread met through taxation. The total amount of the bread provided (units in production) is set by a majority vote, while the distribution of bread (units in consumption) is based on a fixed share arrangement. For example, if the total distribution is 100 loaves per week and Joe's benefit share is .02, then he receives 2 loaves per week. If the distribution scheme is changed—the fixed benefit shares are changed—how does this affect the total amount of bread (in production units) that voters will most prefer? On what factors does each voter's demand depend and how do these individual demands aggregate into market level results?

Section IA examines the individual choice problem: how does an individual's most preferred public sector size change as his benefit share changes? Buchanan (1968, p. 54) conjectures that an individual with

* Assistant professors, department of economics, and research associates, Center for Study of Public Choice, Virginia Polytechnic Institute and State University. We are indebted to the Ford Foundation for financial support of this research. We acknowledge the helpful comments of James Buchanan, Robert Parks and Theodore Bergstrom on earlier drafts of the paper. We are also deeply indebted to our late colleague Winston Bush who helped us launch our joint research. Earlier drafts of this paper were presented at the Southern Economic Association Meetings in Atlanta 1974, and in seminars at the University of Arizona and the University of Illinois.

[1] This distinction is made in Buchanan (1966), further developed in Buchanan (1968, pp. 52–56), and is a major issue in the discussion between Albert Breton and Buchanan (1967).

[2] Recent empirical work has explicitly utilized this distinction by assuming equal sharing in the consumption units. For examples of the use of the equal sharing assumption in the recent empirical literature, see Thomas Borcherding and Robert Deacon, Theodore Bergstrom and Robert Goodman, or Robert Spann.

a higher benefit share would prefer a larger public sector budget. The present paper establishes empirically plausible conditions under which this conjecture is false.[3] If the $i$th voter has price-inelastic (elastic) demand for the production of the publicly provided good, then an increase in his perceived benefit share $\alpha_i$ causes him to prefer and hence vote for a smaller (larger) size of the public sector and its budget. Section IB presents a simple market level example to illustrate the notion of benefit share progressivity and examine the effects of changes in the degree of progressivity on market level outcomes. Finally, Section II applies the analysis to the public provision of a purely private good, bread, and to a more typical public service, fire protection. These applications provide explicit interpretations of the meaning of benefit shares.

## I. The Basic Model

### A. *Individual Level Analysis*

Suppose that the $i$th voter's preferences can be represented by the general utility function:

$$(1) \qquad U_i = U_i(z_i, q_i)$$

where $z_i$ is the voter's consumption of the privately provided good and $q_i$ is the voter's perception of his personal consumption of the publicly provided good. In this section, the voter's perception of his personal consumption is assumed to be a linear function of the total provision of the publicly provided good $x$, i.e.,

$$(2) \qquad q_i = \alpha_i x$$

where $\alpha_i$ is the voter's perception of his benefit share.[4] Generally, the benefit share $\alpha_i$ is considered to be greater than or equal to zero, and less than or equal to unity.[5] The total provision is measured in production units while the individual only values his own consumption units $q_i$.[6]

When voting, each individual determines his most desired provision of the publicly provided good $x$ by maximizing his utility function subject to equation (2) and his budget constraint:

$$(3) \qquad y_i \geqq z_i + p_i^x x$$

where $y_i$ is his income and $p_i^x$ is the price, in terms of the numeraire good $z$, to voter $i$ of an additional unit of $x$. That is,

$$(4) \qquad p_i^x \equiv \tau_i p$$

where $\tau_i$ is the $i$th voter's nonnegative tax share and $p$ is the market price of an additional unit of $x$ in terms of the numeraire good.

By substituting equations (2) and (4) into (3), the voter's maximization problem can be stated as:

$$(5) \qquad \max_{z_i, q_i} U_i = U_i(z_i, q_i)$$

[3] In the present paper, benefit shares are not determined as they might be in a normative model such as Buchanan (1968, pp. 60–65).

[4] Equation (2) implies a system of proportional distribution of the production of $x$. This is also the meaning of Figure 4.1 of Buchanan (1968, p. 59). Much of the meaning of equation (2) can be derived from Buchanan (1968, pp. 52–65). Equation (2) is also identical in interpretation to the $T(.,.)$ map of Charles Plott and Robert Meyer (p. 21). Although they further distinguish between available amounts $q_p^i$ and appropriated units $x_k^i$, most of their discussion involves the distinction between production and consumption units.

[5] Perhaps a better terminology would be to call $\alpha_i$ a coefficient of distribution of the publicly provided production flow $x$. The obvious analogy between benefit share and tax share has a certain appeal, however, and for this reason the expression "benefit share" is used instead of, say, "coefficient of distribution."

[6] The basic function of equation (2) is to provide a definite relationship between the potentially observable public sector state $x$ and the more subjective consumption unit $q_i$, which directly enters the voter's utility function. The production of the publicly provided good $x$ is only potentially observable since the total budget size $px$ is the variable that is generally observable. In short, existing data often just contain total budget size and, hence, it may be difficult to separate quantity and price. In order to avoid the more subjective measurement problems involved in dealing with $q_i$ the attention of this paper is focused on equations dealing with $x$ rather than $q_i$.

subject to $y_i \geqq z_i + \left(\frac{\tau_i p}{\alpha_i}\right) q_i = z_i + \overset{q}{p_i} q_i$

One can treat $p_i^q$ as the price to voter $i$ of *consuming* an additional unit of the publicly provided good—it is his tax price for an additional unit of $q_i$. Under appropriate conditions this maximization problem yields a differentiable demand function of the following general form:

$$\overset{d}{q_i} = g_i(\overset{q}{p_i}, y_i) \tag{6}$$

The demand function given in (6) can be immediately converted into the $i$th voter's demand for the total provision of the publicly provided good $x_i^d$ as a function of the benefit share, tax share, the price of a unit of $x$, and income. That is,

$$\begin{aligned} \overset{d}{x_i} \equiv \overset{-1}{\alpha_i} \overset{d}{q_i} &= \overset{-1}{\alpha_i} g_i(\tau_i p / \alpha_i, y_i) \\ &= h_i(\tau_i p, \alpha_i, y_i) \end{aligned} \tag{7}$$

Voter $i$'s demand for the total provision of the publicly provided good $x_i^d$ is best interpreted as his most preferred or desired public sector size—the quantity associated with the peak of his single-peaked public sector preference relation.[7]

Equation (7) could be used to determine how the voter's demand for $x$ varies with changes in his tax share, benefit share, income, and the price of a unit of the public good ($\tau_i$, $\alpha_i$, $y_i$, and $p$, respectively). The major concern of this paper, however, is with the effects of changes in benefit shares on $x_i^d$. Differentiating equation (7) with respect to $\alpha_i$ and rearranging gives:[8,9]

$$\frac{\partial \overset{d}{x_i}}{\partial \alpha_i} = -\frac{1}{\alpha_i} \overset{d}{x_i}(1 + \eta_{x,p}) \tag{8}$$

The expression can be signed if one knows the price elasticity of demand for $x$, i.e.,

$$\frac{\partial \overset{d}{x_i}}{\partial \alpha_i} \gtrless 0 \qquad \text{as } \eta_{x,p} \lesseqgtr -1 \tag{9}$$

Equation (9) gives the fundamental result of this section for the linear perception relation given by equation (2). In words, *if voter $i$ has price-inelastic (elastic) demand for the production or total provision of the publicly provided good, then an increase in his perceived benefit share $\alpha_i$ causes him to prefer and, hence, vote for a smaller (larger) size of the public sector and budget.*

The basic mechanism for this result is quite simple and is most clearly seen by examining the demand function for $q_i$ along with equation (2). This linear share assumption implies the equality of the tax-price demand elasticities for $x$ and $q$; i.e.,

$$\eta_{x,p} = \eta_{q,p} \tag{10}$$

Now consider voter $i$'s behavior as $\alpha_i$ changes if his demand is price inelastic. In this case, a doubling of $\alpha_i$, causing a halving of $p_i^q$, leads to less than a doubling in $q_i^d$. But equation (2) implies that the doubling of $\alpha_i$ causes a doubling of the amount of the good that is actually available to the $i$th voter for consumption from the *existing* production of the publicly provided good. As a result, the $i$th voter will vote for a smaller total production of the publicly provided good $x$, attempting to bring his actual or perceived consumption of the good into equality with his desired

[7] The voter's public sector preference function provides his ordering of public sector states by assigning a utility level or index to alternate states of the public sector measured in terms of production units. The state of the public sector could also be the total budget size. The quasi concavity of the utility function and the convexity of the budget set in (5) insures the single peakedness.

[8] The elasticity $\eta_{x,p} = (\partial x_i^d / \partial p_i^x)(p_i^x / x_i^d)$, and $\eta_{q,p} = (\partial q_i^d / \partial p_i^q)(p_i^q / q_i^d)$.

[9] At this point it may help to interpret equation (8) in terms of its operational content. First, one may be able to observe the same individual having two different benefit shares: shifts in policy or jurisdictional consolidation could lead to this possibility. Secondly, one might assume that for empirical testing, all individuals have the same tastes, but different benefit shares. A final possibility would involve individuals having different tastes with the benefit shares distributed independently of the taste parameters.

consumption. By a similar argument, if the demand for the consumption of the publicly provided good is elastic, then an increase in the voter's benefit share will cause him to vote for a larger total production of the publicly provided good. Finally, if the elasticity is unitary, then the voter's desired size of the public sector is independent of his benefit share—changes in his benefit share will not affect his voting behavior.[10]

### B. *Market Level Analysis*

The analysis of individual voter behavior in the previous section must be extended to the market level if it is to provide insights into the effects of changes in benefit shares on the equilibrium size of the public sector budget. This section provides an example using the above analysis to generate market level results.

#### 1. *A Simple Model*

The present example introduces the notion of benefit share progressivity and examines the effects of changes in progressivity on market level outcomes. To develop this example, explicit functional forms are assumed for the demand functions, the tax shares, and the benefit shares.[11]

Each voter is assumed to have the following demand function for $q$:

$$q_i^d = \rho_0 y_i^{\rho_1} (p_i^q)^{\rho_2}$$

Substituting in for $q_i^d$ and $p_i^q$ yields from (2) and (6):

$$(11) \qquad x_i^d = \rho_0 y_i^{\rho_1} \tau_i^{\rho_2} p^{\rho_2} \alpha_i^{-(1+\rho_2)}$$

In this example, tax shares are determined by the following function:

$$(12) \qquad \tau_i = \frac{y_i^\beta}{\sum_j y_j^\beta} \qquad j = 1, \ldots, m$$

This formulation of the tax shares may possibly result from a system of property taxation.[12] Finally, perceived benefit shares are also assumed to depend only on income:

$$(13) \qquad \alpha_i = \frac{c y_i^\gamma}{\sum_j y_j^\gamma}$$

Note that the benefit shares sum to $c$. If $c$ equals unity, then the example may involve the case of public provision of a purely private good. The parameter $\gamma$ reflects in some sense the extent to which the distribution of the publicly provided good is biased towards the more affluent groups relative to the situation of equal shares; i.e., $\gamma$ equal to zero and, thus, $\alpha_i$ equal to $c/m$, where $m$ is the total number of recipients of the publicly provided good.

[10] A transparent illustration of this case is provided by the Cobb-Douglas utility function, $U_i = A z_i^a q_i^{(1-a)}$. In this case,

$$q_i^d = (1-a)\frac{y_i}{\left(\dfrac{\tau_i p}{\alpha_i}\right)}$$

and $$x_i^d = (1-a)\frac{y_i}{\tau_i p}$$

In short, the demand function for $x$ does not then depend on $\alpha_i$.

[11] See Bergstrom and Goodman, Borcherding and Deacon, Robin Barlow, and Bergstrom for similar uses of these particular functional forms.

[12] This interpretation is implicit in the work of Bergstrom. To see this interpretation, assume (i) that the only source of taxation is a fixed percentage tax on the market value of residential property; and (ii) that all individuals have the same demand function for housing:

$$Q_i^H = \theta p_H^\mu y_i^\beta$$

The tax bill of the $i$th individual, $T_i$, is, hence,

$$T_i \equiv t P_H Q_i^H = t\theta P_H^{1+\mu} y_i^\beta$$

where $t$ is the real tax rate, adjusted for the assessment ratio, and the total community tax bill $T$ is

$$T \equiv \sum_j T_j = t\theta P_H^{1+\mu} \sum_j y_j^\beta$$

Therefore, the tax share of the $i$th individual is

$$\tau_i \equiv \frac{T_i}{T} = \frac{y_i^\beta}{\sum y_j^\beta}$$

An example of a distribution scheme that leads to equation (13) is one in which the distribution of the benefits of certain governmental services is in proportion to the value of an individual's property holdings.[13] Another example of benefit share progressivity can be derived from the analysis of Buchanan (1971). In this article, the attempt to "bribe" wealthier central city residents not to migrate to the suburbs leads to a distribution of governmental services which may be biased towards the rich.

In the context of a simple majority rule voting system, changes in $\gamma$, the degree of benefit share progressivity, generate comparative static results on a market level variable such as $x$ by affecting the median quantity demanded—the equilibrium provision of the publicly provided good.[14] For each voter, the effect of a change in $\gamma$ on his demand for $x$ is given by:

$$\frac{\partial x_i^d}{\partial \gamma} = \frac{\partial x_i^d}{\partial \alpha_i}\frac{\partial \alpha_i}{\partial \gamma} \tag{14}$$

with

$$\frac{\partial x_i^d}{\partial \alpha_i} = -\frac{1}{\alpha_i} x_i^d(1+\rho_2) \gtrless 0 \qquad \text{as } \rho_2 \lesseqgtr -1$$

The second factor in equation (14) is more complex but is given by:

$$\frac{\partial \alpha_i}{\partial \gamma} = \frac{\alpha_i \sum_j (ln\, y_i - ln\, y_j) y_j^\gamma}{\sum_j y_j^\gamma} \tag{15}$$

For a given value of $\gamma$, the sign of this expression depends solely on the location of the $i$th voter in the income distribution.

In certain cases—given particular values of $\gamma$ and properties of the income distribution—the sign of $(d\alpha_i/d\gamma)$ and, hence, $(dx_i^d/d\gamma)$ can be determined. For the present problem, Lemma 1 of Bergstrom implies that

$$\frac{\partial \alpha_i}{\partial \gamma} < 0 \qquad \text{if } y_i < \left(\frac{1}{m}\sum_j y_j^\gamma\right)^{1/\gamma} \tag{16}$$

For certain cases this result applies to a majority of voters including the median income voter.[15] In these cases, the effect of changes in $\gamma$ on the *equilibrium* provision (or production) of the publicly provided good $x$ as determined through the voting process can also be established.

Bergstrom's work can readily be used to show that:

$$\frac{\partial x}{\partial \gamma} \gtrless 0, \qquad \text{for } \rho_2 \lessgtr -1 \tag{17}$$

if $\gamma \geqq 1$ and $y_{median} < y_{mean}$

In words, if the demand for the total provision of the publicly provided good is price inelastic (price elastic), benefit shares are highly progressive, and the median income is less than the mean income, then increases in the degree of benefit share progressivity lead to an increase (a decrease) in the equilibrium provision of the publicly provided good. (See Bergstrom, p. 190.)

Next, if $\gamma$ is less than or equal to zero, an additional result can be derived. Note that the limit,

$$\lim_{\gamma \to 0}\left(\frac{1}{m}\sum_j y_j^\gamma\right)^{1/\gamma}$$

is the geometric mean income. In this case,

[13] Noel Edelson makes this assumption in his analysis of a local government solely financed by a property tax. In this case, if $c=1$, the property is homogeneous and is the same property as assessed for tax purposes (see fn. 12), then $\gamma$ equals $\beta$ and benefits are distributed in the same manner as tax bills—$\alpha_i$ equals $\tau_i$. In this case, the tax price to voter $i$ of consuming an additional unit of the publicly provided good $p_i^q$ is equal to the market price of an additional production unit, $p$. In addition, if the effect of the public sector is only on property values and not directly on utility at all, then Edelson has shown that the property tax leads to Lindahl equilibrium and is Pareto optimal (see Section II on Lindahl equilibrium).

[14] See Howard Bowen and Duncan Black for a presentation of the median voter analysis.

[15] In the present model, the ordinal positions of income receivers is either the same or reversed in the distribution of demand quantities. In either case, the median income recipient is the median voter, which will be the equilibrium in a majority voting procedure (see Bowen or Black (ch. 1)).

equations (14) and (16) imply that:

$$\frac{\partial x}{\partial \gamma} \lessgtr 0 \quad \text{for } \rho_2 \gtrless -1 \tag{18}$$

if $\gamma \leqq 0$ and $y_{geometric\ mean} \leqq y_{median}$

In words, if the demand for $x$ is price inelastic (price elastic), benefit shares are equal or more regressive, and the geometric mean income is less than or equal to the median income, then increases in the degree of benefit share progressivity lead to a decrease (an increase) in the equilibrium provision of the publicly provided good.[16]

## II. Applications of the Model

The model developed in Section I can be illustrated by applying it to an analysis of: 1) the public provision of a purely private good, bread; and 2) the public provision of fire services. These two examples illustrate several possible interpretations of the benefit shares, and also demonstrate the importance of studying differences in the benefit shares.

### A. *The Public Provision of a Purely Private Good: Bread*

Consider the following simple example. Suppose a government is publicly providing bread to the voters in a community. McTavish (a voter) is initially in equilibrium at his initial benefit share. Due to some change in policy, his benefit share is doubled. The cost to McTavish of the government providing another loaf of bread to the community (distributed according to benefit shares) is unchanged and still equals his tax share times the market price of a loaf of bread. But, the cost to McTavish of receiving another loaf of bread from the government for his own consumption has been halved. Assuming that McTavish has price-inelastic demand, he will increase his demand for loaves (in consumption units) but to less than twice as much. He will, however, if the total provision remains unchanged, get twice as much bread each week, an amount greater than his demand. Therefore, he will prefer to reduce the size of the public sector, reducing his tax bill.

The above analysis applies only when the private market for bread has been abolished. If an individual can buy or sell bread in the private market, then his voting behavior with respect to the public provision of bread is dramatically affected. Suppose first that an individual can buy bread in the private market to supplement his public allocation, but that resale is prohibited. A voter faced with a consumption tax price $p_i^q$ greater than the market price (i.e, $\tau_i > \alpha_i$) will wish to buy his bread in the market and express a zero demand for publicly provided bread. It is clear then that the public provision of bread at a nonzero level will occur only if a majority of voters have tax shares no bigger than their benefit shares.

Next consider the other extreme in which the public provision cannot be supplemented by purchases in the private market, but the individual can adjust his public allocation by reselling the bread to the government at a price of $p$ (or by selling it in the export market). Under these conditions voters with a tax price for a consumption unit $p_i^q$, below the market price $p$, will vote for unbounded increases in the public provision of bread as they can resell the excess beyond their own consumption to the government, making a per unit profit of $(p - p_i^q)$. For equilibrium to exist, a majority of the voters must have tax prices $p_i^q$ greater than or equal to the market price $p$ (or $\tau_i \geq \alpha_i$).

Combining these results leads to the conclusion that for the public provision of a purely private good to continue in the presence of a private, competitive market, allowing for private purchases and resales,

[16] For a sample of Kentucky counties using 1970 Census of Population data, it turns out that the median income is greater than the geometric mean income for each county.

a majority of voters must have tax prices $p_i^q$ of exactly $p$. In short, continued public provision of a freely exchangeable private commodity requires either: 1) outlawing private exchange of the good; 2) a special earmarked tax with tax shares set equal to benefit shares for a majority of voters; or 3) the setting of benefit shares so that they equal the marginal tax shares implicit in the given finance system. Since the occurrence of either of the last two conditions seems improbable, and the criminalization of private markets generates many other problems, it appears unlikely that easily exchangeable goods such as bread could ever be publicly provided in a participatory democracy.[17] This example also leads to one further observation. Those private commodities that it is feasible to provide publicly are likely to be the same commodities that would allow entrepreneurs to practice price discrimination—services such as medical care and fire protection are obvious examples.

### B. *The Public Provision of Fire Services*

Suppose that the governing body of a town is considering the construction of a firehouse of a certain size. Ignoring the road network, a voter in this town would generally perceive himself to be receiving a larger quantity of fire services if the station is closer to his residence. In terms of the notation of the present paper, the $i$th voter's benefit share $\alpha_i$ is negatively related to the distance of his residence from the firehouse.[18] In these circumstances, if $x$ represents the size of the firehouse, then $\alpha_i x$ is the $i$th voter's perception of the quantity of fire services available to him. Finally, assume that the voter only cares about the fire services provided directly to him.[19]

The application of the present model to this example involves a particular restriction on preferences. Let $d_i$ be the distance that voter $i$'s home is from the firehouse of size $x$. If the voter's preferences are assumed to be representable by

$$U_i = U_i(z_i, x, d_i) \tag{19}$$

then, for the present formulation to be correct, there must exist a function $e(d)$, such that

$$\alpha_i = e(d_i), \qquad e' < 0 \tag{20}$$

and

$$U_i(z_i, x, d_i) = V_i(z_i, \alpha_i x) \tag{21}$$

That is, preferences must be separable as between $(z_i)$ and $(x, d_i)$; i.e., the marginal rate of substitution ($MRS$) between $x$ and $d_i$ is independent of the value of $z_i$. If preferences do not exhibit this separability, then no amount of effort applied to the analysis of the "technological" relation, equation (2), will yield correct results. The distinction between units in production and units in consumption leads to some useful results, but this distinction is not primary. Rather its validity depends upon the form of consumer preferences.

The analysis based on equations (7) and (9) now applies. If the voter has price inelastic demand for fire services, then as the proposed fire station is moved closer to his house, he will desire and vote for a smaller size fire station since his benefit share increases from equation (20). This result does not seem at all unusual, as the closer fire station provides him with a greater amount of fire protection, reducing its marginal value to the voter (his $MRS$ diminishes), hence causing him to wish to

[17] See Gordon Tullock on the likely results of such criminalization.

[18] The interpretation one attaches to $\alpha$ and their resulting properties vary with the problem being examined. Note that in the earlier example of Section II in which bread, a purely private good, is publicly provided, the benefit shares are the actual proportion of the total supply received by each voter and must sum to one. In this firehouse example, no such restriction is implied.

[19] Actually, $\alpha_i x$ could represent the level of fire services for an entire neighborhood, as perceived by the $i$th voter.

substitute lower taxes for fire station size.

Benefit taxation is often suggested for the financing of public goods. In particular, Lindahl tax prices have been analyzed as they lead to both optimality in the level of provision as well as unanimous agreement as to this level. Both results hold if one can find a vector of tax prices, $(p_1^x, \ldots, p_m^x)$, such that the quantity of $x$ demanded is the same for all voters, since on the demand function, tax price is equated to the *MRS* for the public good. Thus, the distribution of Lindahl tax prices will be the same as that of the *MRS*.

If voters have similar tastes and price-inelastic demand for fire services, then the Lindahl tax prices will be *lower* for these consumers closer to the firehouse and *higher* for those further away (given that they have the same income). Thus voters who receive more fire services pay smaller tax bills. This result is quite different from the tax systems used in highway or sewer finance in which tax shares are related positively to benefit shares. The differences follow from the fact that the Lindahl system ignores total benefits and instead deals only with marginal quantities.

# The Non-Uniqueness of Equilibrium in the Löschian Location Model

*By* B. Curtis Eaton and Richard G. Lipsey*

The great emphasis placed on regular hexagonal market networks in location theory suggests a presumption that: 1) this network is the unique equilibrium configuration when the number of firms in the market is given, and 2) free entry will cause this network to prevail. These presumptions have been prevalent in the literature since the monumental work of August Lösch. In this paper we argue that both presumptions are wrong: the regular hexagonal lattice is only one of a large number of equilibrium configurations, and free entry does not necessarily produce regular hexagons.

It is well known that (subject to the condition that every point in the space be served) the hexagonal network of market boundaries would be the planner's solution.[1] This result is not at issue here. The question that we consider is whether or not free competition, with each firm seeking to maximize its own profits, will bring about the hexagonal configuration of firms. If this question is to be studied satisfactorily, it is important not to assume the answer at the outset, but rather to make behavioral assumptions suitable to the decisions of independent firms and households and then to determine whether or not the hexagonal configuration will result from the assumed behavior.

In Section I of this paper we analyze a simple model designed to deal with this question. In Section II we relax some of the model's more restrictive assumptions. In the concluding section we discuss the reasons why our results differ from those that appear to follow from Lösch's famous treatment of the same problem.

## I. The Analysis of the Simple Model

### A. *The Model*

We begin by listing and discussing the assumptions of our model.

(a) The infinitely extensible plane is uniformly populated with customers with a density of one per unit of area.

(b) Each firm is faced with the same total cost function, $TC=K+cQ$, where $K$ is fixed costs, $c$ is the constant marginal cost of production, and $Q$ is quantity produced and sold. This cost function is commonly used in location theory and we can take $c$ as zero without loss of generality.

One way in which such a cost function could arise is through indivisibilities. To rationalize this precise function in this way we can assume that the only fixed costs are those associated with capital, and that there is an indivisibility in plant size such that the smallest possible plant is large enough to serve any of the markets for individual firms that we consider. We thus have $K=rI$ where $r$ is the opportunity cost of capital and $I$ is the investment associated with the minimum possible size of plant. Since indivisibilities are ubiquitous with any production involving machines,

We wish to acknowledge the helpful comments and suggestions of many colleagues, the valuable research assistance of Edward France, Allan Popoff, and Duncan Smeaton, and the generous support of the Queen's Institute for Economic Research.

[1] See Belá Bollobás and Nicholas Stern for a recent example of a full discussion of this proposition.

our cost assumption is not empirically uninteresting.[2]

(c) Transport costs per unit distance are constant. Consumers bear the cost of transport.

(d) Consumers buy from the firm whose delivered price is lowest.

(e) All firms charge the same mill price which is an exogenously imposed constant (the common mill price must exceed $c$ and it is taken to be unity).

Assumptions (d) and (e) together imply that the market boundary between two adjacent firms is the perpendicular bisector of the line joining the two firms. Thus each firm's market is defined by a set of linear boundary segments whose positions depend solely on the locations of the firm and its neighbors. Assumption (e) allows us to concentrate on spatial rather than on price competition, but it is not necessary for the results that we obtain. The consequences of dropping it are considered in Section II.[3]

(f) All customers buy one unit of the product per period of time. This assumption greatly simplifies the analysis and exposition, but it is not necessary for the results that we obtain. The consequences of dropping it are also discussed in Section II.

(g) In selecting its location, each firm seeks to maximize its profits and takes the location of all other firms as given, i.e., it has a zero conjectural variation ($ZCV$). With respect to location $ZCV$ is an appropriate assumption in at least two important cases: 1) where equilibrium is approached very rapidly so that firms do not have time to learn their opponents' reactions; and 2) when relocation occurs (if at all) only after a very long time lag, as in many locational problems.[4] (Since our firms are engaged in noncooperative games, any equilibria that we discover will be Nash equilibria.)

The assumptions made above affect the measurement of our profit variables. *Gross profit* $R$ is total revenue minus total variable cost: $R=PQ-cQ$. Since we have assumed $c=0$ and $P=1$ and, since each unit of market area contains one customer who buys one unit of the product per period of time, we have $R=Q=$ *Market Area. Pure profits* $Z$ (also called net profits) are gross profits minus total fixed costs: $Z=R-K$. Thus in the model of this section, maximizing profits is the same thing as maximizing market area.

[2] As Nicholas Kaldor puts it, "Yet on an empirical level, nobody doubts that in any economic activity which involves processing or transforming basic materials—in other words, in industry—increasing returns dominate the picture for the very reasons given by Adam Smith in the first chapter of *The Wealth of Nations:* reasons that are fundamental to the nature of technological processes and not to any particular technology" (p. 1242). See also Paul Samuelson. Indeed if there were no indivisibilities and genuine constant returns to scale everywhere in a spatial economy in which transport costs were positive, then there would be no firms at all since all production would take place at the point of consumption so as to reduce transport costs to zero.

[3] It is important to note that our model with a parametric price that is common to all firms will have comparative static properties that are qualitatively similar to those of other models of price competition in which there is a single equilibrium price common to all firms. Consider, for example, the comparative static properties that are implied by the price-conjectural variation that is implicit in Edwin Mills and Michael Lav, and explicit in Martin Beckmann (1971). These authors assume that when setting its price, the firm assumes that each of its competitors will adopt the same price. With this assumption, as with our parametric price, the firm's anticipated market area is independent of the firm's own price. In the Mills-Lav and Beckmann case the existing firms charge the common profit-maximizing price and the general level of profits is raised or lowered by exit or entry. In our model the firms charge a common arbitrary price and the general level of profits is raised or lowered by exit or entry. Indeed anything that we prove for any arbitrary price must be true for one particular price, the monopoly price. Qualitatively these models behave in a similar fashion with respect to spatial competition.

[4] This does not mean that relocation never occurs, but only that the firm's locational decision is taken on the assumption that *over the relevant planning horizon* other firms will not relocate in response. Of course other conjectural variations can be studied, but in each new case the conditions of equilibrium will have to be suitably amended.

These assumptions outline the simplest model that will do our job. We wish to consider the conjectures: (i) that the Löschian hexagonal pattern is the unique equilibrium configuration on the infinitely extensible plane, and (ii) that if other configurations are arbitrarily imposed, the process of entry of new firms will convert these into hexagonal configurations. Our model provides a counterexample which is sufficient to refute both of these conjectures. It also shows some other configurations that can sometimes produce equilibria and it allows us to examine the relative stability of each of these under conditions of entry. In Section II we relax some of the assumptions of this model in order to deal with the possible objection that our assumptions are so restrictive that our counterexamples are of no real interest other than as pathological cases.

### B. *The Technique of Analysis*

We analyze the behavior of our model using numerical simulation techniques. We do this because most of the questions we wish to ask are extraordinarily difficult, if not impossible, to answer using conventional analytical methods.

Where they are feasible, analytical techniques are usually preferable to numerical simulation techniques. Numerical methods can prove, for example, that a given configuration *is not* an equilibrium configuration by demonstrating the existence of a profitable move. They cannot, however, prove that a particular configuration *is* an equilibrium configuration. They are only strongly suggestive. The inevitable rounding errors of simulation routines limit the fineness of the grid of potential locations, and in any case it is impossible to evaluate potential profits at an infinite number of points. We have used numerical techniques solely because the problem seemed intractable with conventional analytical techniques, while numerical techniques do seem to allow us to proceed further than other investigators who have confined themselves to analytical methods.

The core of our technique is an algorithm (described in detail in our 1972a paper), which answers the following question: given the location of $n-1$ firms in some region of the infinitely extensible plane, what market can the $n$th firm expect to control if it locates at an arbitrary point in the region?[5] Using this algorithm it is an easy matter to produce a map which describes the profits that the $n$th firm could expect to have if it located at any one of a large number of alternative points, given the locations of all of its neighbors. We refer to such maps as market maps.

Figure 1 reproduces a part of one of these maps. The origin is shown by the dot within the circle, and the dots are spaced four units apart vertically and horizontally. The neighbors of the $n$th firm are shown by circled crosses. The numbers without parentheses indicate the $n$th firm's market area and hence by the assumptions in Section I, its gross profits in each of the positions indicated by the dots. Thus, for example, if the firm locates at the origin, its market area, and hence its profits, are 692 while if it locates at the point (8, 4) they are 698. (The numbers in parentheses show the profits in each loca-

[5] The algorithm was developed to analyze locational problems in a bounded market (see the authors, 1975a), but is easily adapted to the study of some types of behavior in infinitely extensible Löschian space. The basic analytical difference between unbounded and bounded space is that in the former a firm's market boundary must be composed entirely of boundary segments with other firms, whereas in bounded space a firm's market boundary can coincide over some of its range with the boundary of the market. Consider the problem of determining a firm's market area at some particular point in infinite space. The firm will, at least in all the cases in which we are interested, have a boundary with a small number of neighboring firms. The market area algorithm for the bounded space is adapted to the problem of a firm locating at a particular point in unbounded space simply by including all of the neighboring firms in the bounded space.

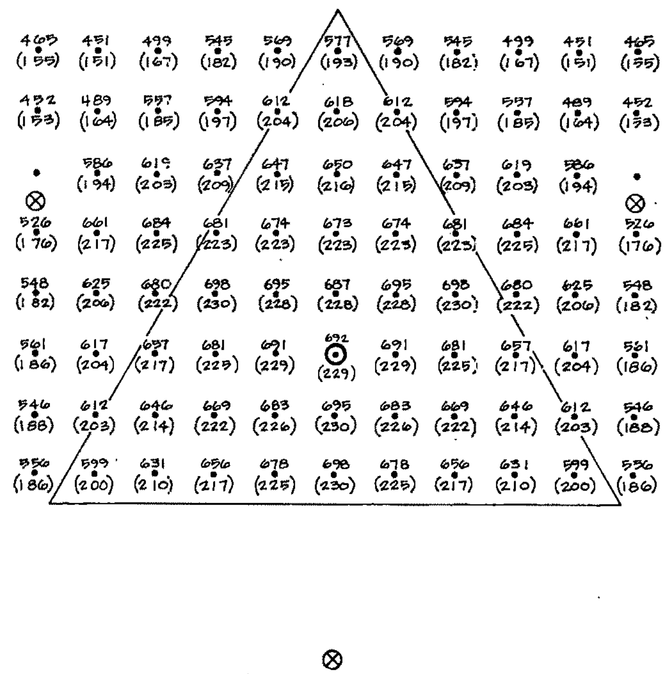

FIGURE 1. THE ABSENCE OF EQUILIBRIUM IN A NETWORK OF EQUILATERAL TRIANGLES

The numbers show the profits the $n$th firm would make by locating alternatively at each of the dots and with neighbors in the fixed positions shown by the circled crosses. Numbers in parentheses refer to the model of Section II, numbers not in parentheses refer to the model of Section I. Location of the $n$th firm at the origin, the point inside the circle, completes the symmetrical lattice of firms and gives the $n$th firm the market boundaries indicated by the dashed lines. Rows and columns are separated by 4 units in Figure 1 and by 6 units in all other figures.

tion that arise from the model in Section II.)

In our actual program, profits were calculated for many more points than are shown in our figures. Only 1/16 of the points are shown in Figure 1, and 1/36 of the points in all other figures. Furthermore, if we were uncertain about the precise location of a particular equilibrium, we could magnify any particular part of the market by placing our observation points as close together as we wished.

### C. *Equilibrium in the Absence of Entry and Exit*

We now pass to a consideration of the behavior of our model. We consider, first, a situation in which firms are allowed neither to enter nor to leave the market. In the absence of entry and exit there is a single condition that is necessary and sufficient for all firms in the market to be in equilibrium:

Equilibrium Condition (i): *No firm can find a new location that offers it a larger anticipated profit (assuming ZCV) than that obtained in its present location.*

We first ask which of the three configurations of regular, space-filling polygons (triangles, squares, and hexagons) satisfy equilibrium condition (i). It is interesting that no answer to this question appears to exist in the literature. The reason probably lies with the extreme diffi-

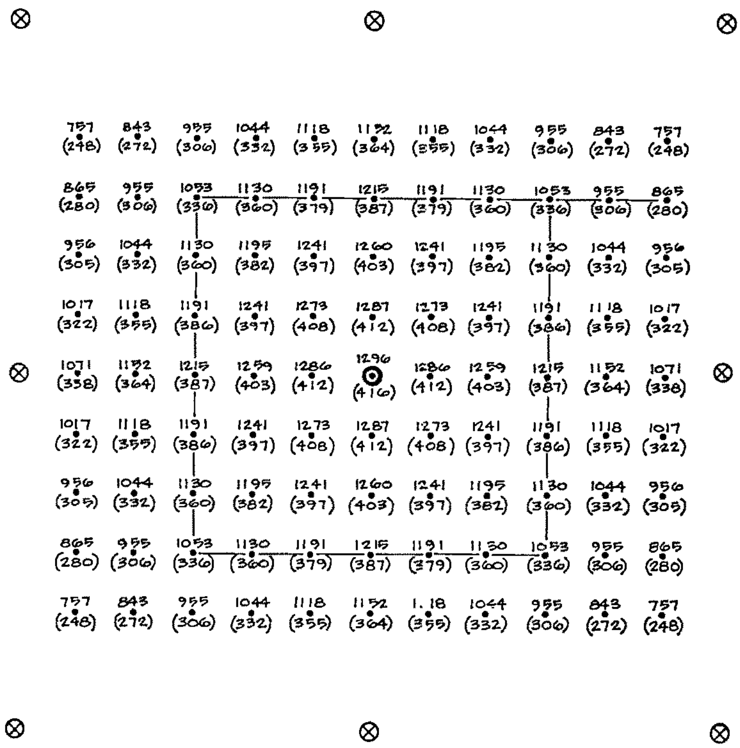

FIGURE 2. EQUILIBRIUM IN A NETWORK OF SQUARES
For the description, see Figure 1.

culty of using conventional analytical methods to deal with such problems.

To answer this question using our technique, we let all the firms be first arranged so that the network of market boundaries is composed of equilateral triangles. We select one firm and make its location the origin. We allow that firm to consider a large number of alternative locations and calculate the market area and hence the profits that it would obtain in each location. The triangular configuration is an equilibrium configuration if and only if the best location for the firm is at the origin. Next, repeat the experiment with the firms arranged so that there is a square network of market boundaries and, finally, so that there is a regular hexagonal network of market boundaries.

Figures 1, 2, and 3 show the results. Intuition suggests and calculation confirms that the firm is always better off remaining within the area defined by its present neighbors rather than moving outside of that area to relocate in an already complete portion of the lattice of firms. Our maps are thus confined to this area. The broken lines indicate the firm's market boundaries when it locates at the origin, thus completing the regular lattice of firms.

Figure 1 shows that the triangular configuration does not satisfy condition (i): the firm at the origin, and hence *any* existing firm, wishes to relocate. The firm would prefer to locate at any of the three locations $(-8, 4)$, $(8, 4)$, or $(0, -8)$ where profits are 698 rather than at the origin where profits are only 692. Thus, given a chance, any firm will move from its posi-

FIGURE 3. EQUILIBRIUM IN A NETWORK OF REGULAR HEXAGONS

For the description, see Figure 1.

tion in a regular triangular lattice. Figures 2 and 3 show that both the square and hexagonal configurations appear to satisfy condition (i): the firm at the origin, and hence any existing firm, does not wish to relocate since the market area and profits at the origin are higher than those at any other location. Thus two of the possible configurations of regular, space-filling polygons satisfy condition (i).

So far we have followed established practice in considering only those configurations of firms that give rise to identical, regular, space-filling polygons. We easily found counterexamples, however, to the conjecture that the only equilibrium configurations were regular, space-filling polygons. We found, for example, that some configurations of identical rectangles would fulfill equilibrium condition (i). Specifically, we discovered by numerical experimentation that condition (i) is fulfilled by any rectangular lattice of market boundaries in which the ratio of the long to the short side of the rectangle is 26:10 or less. Figure 4 provides an example in which the ratio of the sides is 2:1. The figure shows that a firm that is surrounded by a rectangular lattice of other firms maximizes its market area and its profits (at a value of 968 in the present example) by locating at the origin, thus completing the rectangular lattice.

A network of firms and market boundaries composed of irregular hexagons also fulfills condition (i). In Figure 5 the firm that is free to move chooses to locate at the origin, earning gross profits of 1224 and completing the lattice of irregular hexagons. When it does this, each firm is

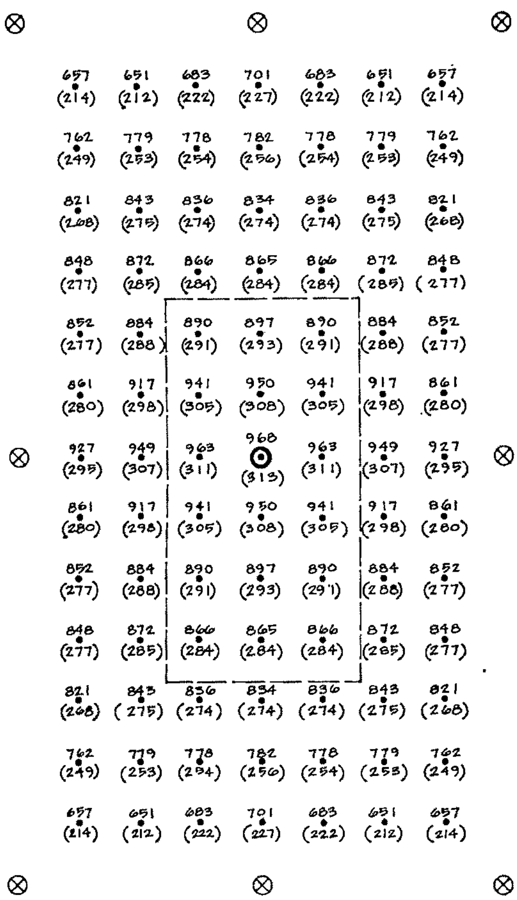

FIGURE 4. EQUILIBRIUM IN A NETWORK OF RECTANGLES WHOSE SIDES STAND IN THE RATIO 2:1

For the description, see Figure 1.

separated from two of its neighbors by 35 and from the remaining four neighbors by 39. This result shows that equilibrium condition (i) can be fulfilled by some configurations that give the firms identical, but nonregular, hexagonal market boundaries.

Our results suggest the further questions: "Can condition (i) be fulfilled: (a) if firms have markets that are not identical in shape but which are equal in area, and (b) if firms do not even have equal market areas?" Although we have not been able to show that identical market shapes or even equal market areas are required by our assumptions, neither have we yet succeeded in finding a configuration of nonidentical markets that satisfies condition (i). *In everything that follows, the argument is confined to situations in which the equilibrium configuration gives all firms markets that are identical in size and shape.*

### D. *Equilibrium Configurations Under Freedom of Entry and Exit*

We now consider the case in which firms are permitted to enter and to leave the market. Condition (i) remains an equilibrium condition, but there are now two further conditions.

Condition (ii): *All possible locations for a new entrant within the network of existing firms offer anticipated gross profits, $R^e$, of less than K.*

Condition (iii): *No existing firm earns actual gross profits, $R^a$, of less than K.*

Taken together, (i), (ii), and (iii) are necessary and sufficient conditions for equilibrium in our free-entry model: (i) ensures that no existing firm wishes to relocate elsewhere in the market; (ii) ensures that no new firm wishes to enter; and (iii) ensures that no existing firm wishes to exit.

We now ask: Which of the configurations that satisfy condition (i) will also satisfy conditions (ii) and (iii)? Our measure of density of packing $h$ is the reciprocal of the distance from a firm to its nearest neighbor. Within any configuration which gives all firms identical markets this definition of density of packing involves no ambiguity.[6]

[6] This definition of density of packing is sufficient for our purposes. In configurations composed of any one of the three regular space-filling polygons the distances to all neighbors are the same. In the irregular configurations that we consider, networks of irregular hexagon and the rectangles, there is no ambiguity in the measure since we hold constant the relative distances from a

FIGURE 5. EQUILIBRIUM IN A NETWORK OF IRREGULAR HEXAGONS
For the description, see Figure 1.

We consider a particular configuration that gives all firms identical markets, which means that the ratios of the distances from a firm to each of its neighbors is held constant. We then vary the density of packing thus changing the absolute distances from each firm to each of its neighbors. The market area, and hence the gross profit of each existing firm, is a monotonically decreasing function of $h$: $R^a = R^a(h)$, with the properties

$$\frac{dR^a}{dh} < 0, \qquad \lim_{h\to 0} R^a = \infty$$

and $\lim_{h\to\infty} R^a = 0$

Now let $R^e$ be the anticipated gross profits of a potential new entrant in its best possible location. Since the profits that a new firm can expect to earn (on a *ZCV* assumption) can be expressed as a function of the profits earned by existing firms which are in turn a function of $h$, we express $R^e$ also as a function of $h$: $R^e = R^e(h)$.

Condition (ii) is fulfilled whenever $R^e(h) < K$. Condition (iii) is fulfilled whenever $R^a(h) \geq K$. Any new entrant must fit into an already completed lattice of firms and must expect to earn profits that are substantially lower than those earned by existing firms before entry occurs. Thus for any given value of $h$, $h_0$, $R^e(h_0) < R^a(h_0)$. To illustrate, numerical calculations show the ratios for $R^e/R^a$ to be approximately 0.51 for a regular hexagonal configuration of firms, 0.56 for a square configuration, and 0.50 for a configuration of rectangles

firm to each of its neighbors. We hold the relative distances constant because we are only interested in whether or not a configuration can be made to satisfy the conditions for entry equilibrium by changing the density of packing. For a general, rigorous treatment of density of firms per unit of market area see Bollobás and Stern.

where the ratio of the lengths of the market boundaries is 2.0. (Although $R^e$ and $R^a$ are both functions of $h$ their ratio is independent of $h$ in each of the configurations that we consider.) It follows immediately that for any configuration of firms that satisfies condition (i), we can find a *range* of values for $h$ that will allow conditions (ii) and (iii) to be fulfilled simultaneously.[7]

Thus the answer to the question with which we began this section is simply that any of the configurations that give identical market areas and that satisfy condition (i) can be made to satisfy (ii) and (iii) by packing the firms closely enough together so that the expected gross profit of any new entrant is less than $K$ and far enough apart so that the actual gross profit of any existing firm is $K$ or more.

It follows that equilibrium in our free-entry model is consistent with a multiplicity of configurations of firms (squares, rectangles, irregular and regular hexagons), and with a *range* of density of packing of firms (and hence of profits for each firm) in *each* of these configurations. The second of these conclusions has already been stated by Beckmann for hexagons (1968, p. 44). The first conclusion does not seem to have been stated in the literature before. We wish to emphasize that the multiplicity of equilibrium configurations would continue to exist even if zero profits were made a condition of equilibrium. For any of our configurations that satisfy condition (i) there is always a density of packing that will make profits exactly zero, thus satisfying conditions (ii) and (iii) at zero profits.

### E. *The Effect of the Process of Entry on the Configuration of Firms*

We may wonder if the dynamic process of free entry is more likely to produce one of the equilibrium configurations, particularly regular hexagons, rather than any other. To consider this, we focus on two specific questions. Does the process of free entry into a square or rectangular configuration of firms tend to transform it into the regular hexagonal configuration? Does the process of free entry into a regular hexagonal configuration tend to reproduce a regular hexagonal configuration?

Many entry dynamics are possible. The one that we use is based on a dynamic suggested for one-dimensional markets by H. Stephen Grace. We discover the set of points of entry offering the highest possible anticipated profits, on the assumption that there is only one new entrant. We then assume that there is simultaneous entry of one firm at each of these points.

Since we know from the previous section that any configuration in which condition (i) is satisfied for all firms can also be made to satisfy conditions (ii) and (iii) by suitable choice of $h$, we concentrate only on condition (i) in the entry process. This allows us to avoid a lengthy discussion of special cases which obscures the main points of interest.[8]

We first consider entry into a network of rectangular markets (in which lengths of the long and short sides of the market boundaries are $X$ and $Y$). A new entrant's most profitable location is at the midpoint of the short side of an existing firm's mar-

[7] To show that $R^e(h_0)<R^a(h_0)$ when condition (i) is satisfied for all existing firms, we use a proof by contradiction. Assume that condition (i) is satisfied for all existing firms (each of whom is making profits of $R^{a*}$ before a new firm enters the market). We denote the profits that a potential new entrant expects as $R^{e*}$. If $R^{a*}<R^{e*}$, the assumption is obviously contradicted, since the entry position was available to any existing firm. If $R^{a*}=R^{e*}$, the assumption is also contradicted. Let $(x_e, y_e)$ be the new entrants' best location, and $(x_i, y_i)$ be the location of its $i$th neighbor. If the $i$th neighbor had chosen the point $(x_e, y_e)$ before the new firm entered, it would have had profits greater than $R^{e*}$ because it would not have had a neighbor at $(x_i, y_i)$. Thus if $R^{e*}$ were equal to $R^{a*}$, then the $i$th neighbor could have had profits greater than $R^{a*}$ if it had located at $(x_e, y_e)$; this contradicts the assumption that condition (i) is satisfied for the $i$th neighbor at the point $(x_i, y_i)$.

[8] See our (1972b) paper for a full discussion of these lengthy obscurities.

ket boundary.[9] When firms enter at each such point, the number of firms is doubled, and a new configuration of rectangular market areas (with sides of lengths $X/2$ and $Y$) is established. Thus the ratio of the long to the short side is changed by entry, but a new configuration of identical rectangular market areas is established.[10] If the configuration satisfied condition (i) before entry, it must satisfy it after entry.[11] Thus rectangles beget rectangles after each round of entry.

We next consider entry into a square network. To obtain the results shown in Figure 6, firms were placed in a square lattice and a single new entrant was allowed to calculate its market area, and hence its profits, at a large number of alternative entry points. The figure shows that the most profitable location for a new entrant is at the midpoint of each of the existing market boundary segments (where profits are 729). Letting a firm enter at each of these points produces the configuration shown by the circled crosses (original firms) and the dots (new entrants) in Figure 7. Condition (i) is no longer satisfied for the original firms. (The diamond in the top left-hand corner of Figure 7 shows one of the best possible points for relocation of the original firms; and such points recur throughout the market in similar locations.) *If* profits after entry were high enough to encourage a second round of entry and *if* this entry occurred before any relocation of firms already in the market, the square network would then be reestablished. The locations of the firms that would come into the market on the second round of entry are shown by the triangles in Figure 7. Condition (i) is now satisfied for all firms. Thus, squares beget squares but only after two rounds of entry and a fourfold increase in the number of firms.

Finally, we consider entry into a hexagonal network. Because the hexagon does not easily reproduce itself, the entry results are complex and their description becomes tedious. We nonetheless thought it worth briefly describing the process because of the enormous amount of attention that has been paid in the literature to the hexagonal configuration.

Beckmann (1968, p. 44) conjectured that a new entrant would wish to locate at the centroid of the equilateral triangle defined by three contiguous firms. If we let a firm enter at each such point, the number of firms is tripled and all firms again have identical, regular, hexagonal market areas. When we applied our simulation model to the entry problem in a hexagonal network, we discovered that Beckmann's conjecture does not apply in our model.[12] Figure 8 shows the market areas for a new

[9] We have not reproduced the map for the rectangular case since it is so similar to the square case shown in Figure 6. In the square the best entry points bisect all the sides of the existing firms' market boundaries.

[10] The original ratio of the long to the short side of the market is $X:Y$. There are several cases: (a) $Y<X<2Y$. After entry, $Y$ becomes the long side and the new ratio becomes $2Y:X$. After a second round of entry the ratio becomes $2X:2Y$ which is, of course, the original ratio. In the special case in which $X:Y=\sqrt{2}$ the ratio is unchanged after each round of entry since if $X/Y=\sqrt{2}$, then $2Y/X=\sqrt{2}$; (b) $X=2Y$. One round of entry creates a square configuration and after this the analysis of entry into square markets is appropriate. This is the special case in which rectangles do not beget rectangles; (c) $2Y<X$. In this case the short side remains the short side after entry, and the ratio of the long to the short side becomes $X:2Y$. Entry proceeds through $r$ rounds until $X<2^rY$ and after this the analysis of case (a) applies.

[11] a) If $X<2Y$, the ratio of the long to the short sides alternates between two values $X:Y$ and $2Y:X$ which must both lie between the bounds of 1 and 2. b) If $X>2Y$, the ratio declines through successive rounds of entry until it reaches a value of less than 2 after which it alternates as in a) above. Thus, if the ratio of the sides is small enough so that condition (i) is satisfied in the initial configuration, entry can never cause it to increase to the point at which condition (i) is not satisfied.

[12] Beckmann's analysis appears to refer to any downward-sloping linear demand curve. Section II below shows that our results generalize at least to some downward-sloping demand curves and that Beckmann's conjecture cannot therefore be correct in general.

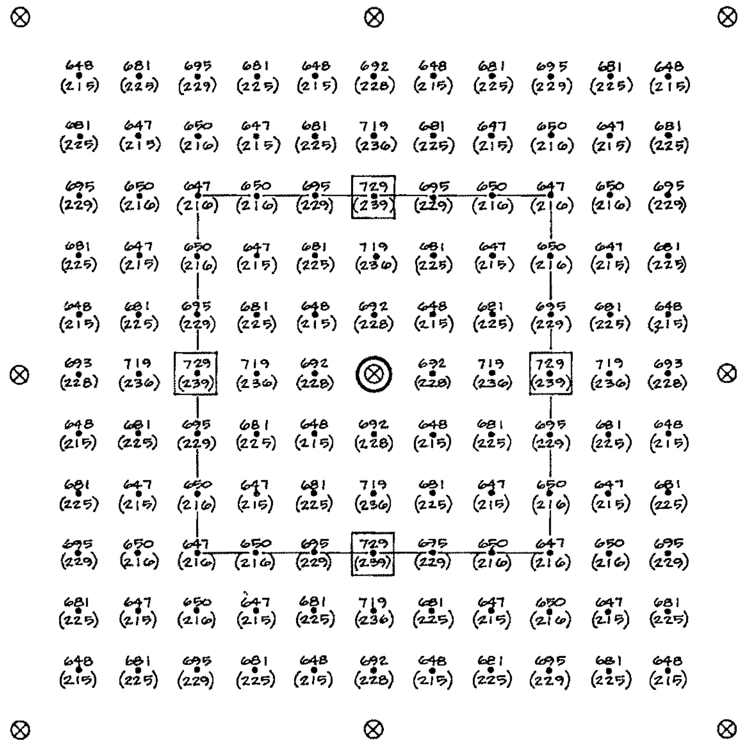

FIGURE 6. ENTRY INTO SQUARE NETWORK

The *n*th firm is located at the origin. Its location is shown by the double circled cross and its market boundaries by the broken lines; its neighbors are shown by single circled crosses. The numbers (in parentheses for the model of Section II and not in parentheses for the model of Section I) show the gross profits available to a single new entrant if it were to locate alternatively at each of the positions indicated by the dots. The best entry points are indicated by squares around both the dot that indicates the exact best point and the numbers that indicate gross profits at that point.

entrant in a number of alternative locations when existing firms are located in a hexagonal configuration at the circled crosses. Beckmann's conjectured entry points are shown by the six points marked with triangles. The market-maximizing entry points turn out to be much closer to the existing firms than Beckmann conjectured. The best entry points close to the firm located at the origin are marked by squares, and there are six such points around each of the existing firms. (The gross profits at these best entry points are approximately 708 while they are 692 at Beckmann's conjectured entry points. Note that because we are only reporting 1/36 of our actual observations our reported observations are close to but not actually at the best points.) If we let a new firm enter at each of the best entry points, we obtain the configuration shown by the circled crosses (original firms) and the dots (new firms) in Figure 9. This is not an equilibrium configuration since condition (i) is no longer satisfied for the original firms. These firms now find themselves surrounded by six very near neighbors and they could substantially increase their market areas by relocating. (The best places to relocate are shown by the triangles in Figure 9.)

In order to carry the analysis a stage

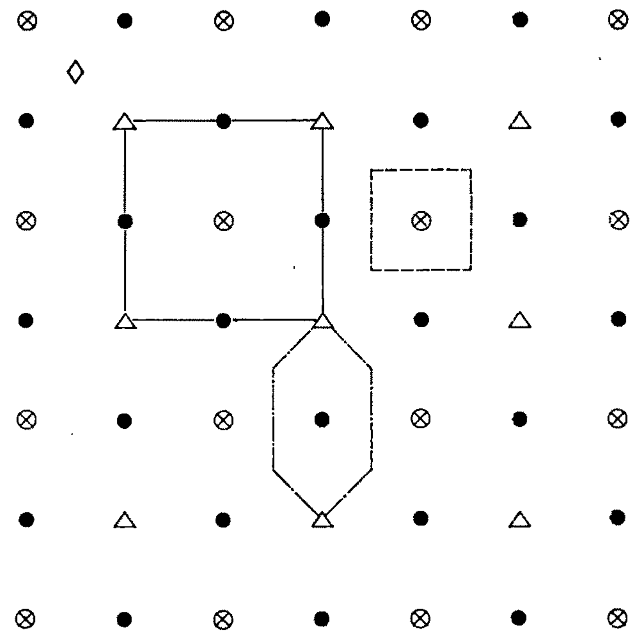

FIGURE 7. ENTRY INTO A SQUARE NETWORK

1) The original firms are shown by circled crosses. The market boundary of one such firm is shown by the solid lines. 2) The locations of new entrants after one round of entry are shown by dots. The market boundary of one such firm is shown by the dot-dashed line. 3) The locations of the new entrants after the second round of entry are shown by the triangles. The market boundary for one such firm is shown by the dashed lines (all firms, old and new, have identical market boundaries after the second round of entry).

further, we consider the effects of further rounds of entry that occur *before* existing firms are allowed to relocate. The second and third rounds of entry are shown in Figure 9 by the triangles and the squares, respectively. The second round still leaves a very irregular network of firms but a third round, if it occurs, reestablishes a hexagonal network. The three rounds, however require a twelvefold increase in the number of firms and, furthermore, the new configuration is not one of regular hexagons. There are no less than four types of market areas. The original firms have regular hexagonal markets, the firms that entered in the three rounds of entry all have irregular hexagonal markets. Condition (i) is not satisfied for the firms that entered in the first and second rounds of entry.

Finally, consider allowing those existing firms for which condition (i) is not fulfilled to relocate. We allow all of the firms that entered in the first round to relocate to their market-maximizing position. The first-round-entry firms are shown with a dot and the desired relocation is shown for six of them by the arrows in Figure 9. Calculation of the market-maximizing locations for these firms shows that this one set of movements establishes a regular hexagonal network of firms and no further movement is desired by any of the firms in the market.

The most important of our entry results may now be summarized. Entry into a square or a rectangular lattice does not tend to turn it into a hexagonal lattice. One round of entry into a hexagonal (or a square) lattice produces disequilibrium

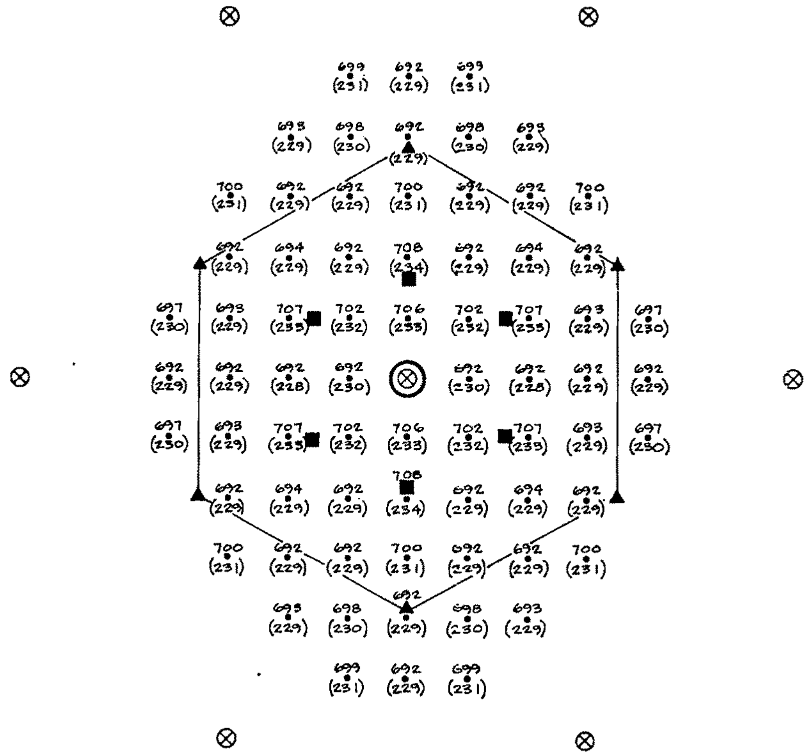

FIGURE 8. ENTRY INTO A REGULAR HEXAGONAL NETWORK

The *n*th firm is located at the origin. Its location is shown by the double circled cross and its market boundaries by the broken lines; its neighbors are shown by single circled crosses. The numbers (in parentheses for the model of Section II and not in parentheses for the model of Section I) show the gross profits available to a new entrant who locates alternatively at each of the positions indicated by the dots. Simultaneous entry at the points indicated by triangles would recreate a hexagonal configuration. The best entry points, however, are those indicated by the squares.

which tends to destroy the lattice. Of the three, therefore, the rectangular lattice seems to be the most robust and the hexagon the least robust in the face of the type of entry that we have considered.

## II. Elasticity of Demand and Price Competition

In this section we relax two of the most restrictive assumptions of our model. In order to focus on the nature of equilibrium configurations in space, we have so far used a model in which the individual consumer's demand is perfectly inelastic (assumption (f)), and we have abstracted from price competition (assumption (e)). These restrictive assumptions considerably simplify the analysis and the exposition of the model but it is important to ask if they are necessary for the results that we obtain. In this section we simultaneously relax both assumptions and demonstrate that our results are not dependent on them.

We now assume that all individuals have the same downward-sloping demand function of a particular form and that firms maximize with respect to price as well as location. The demonstration that our results hold for a particular demand function and a particular type of price competition

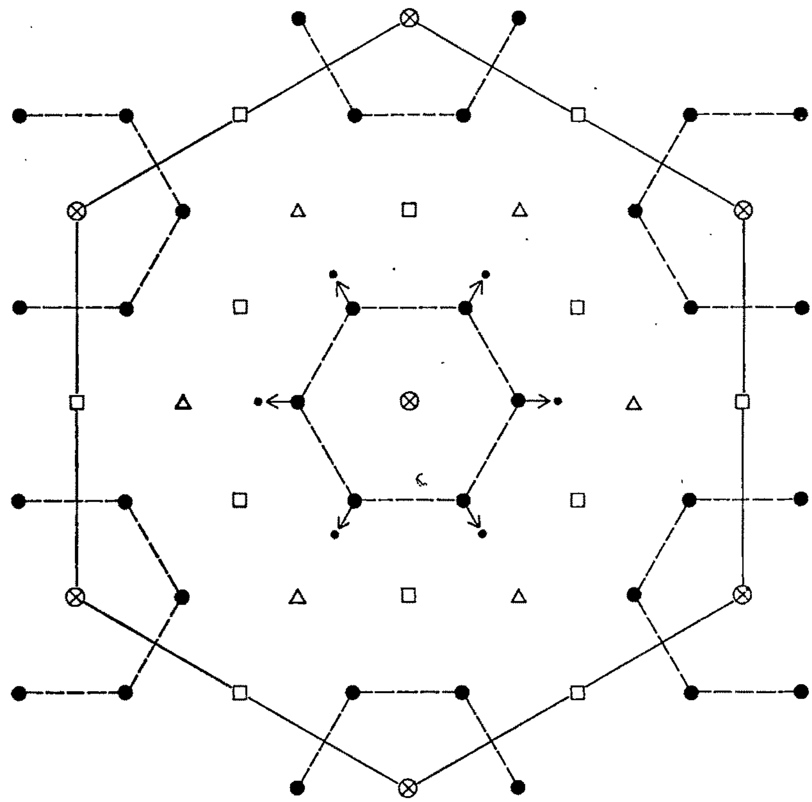

FIGURE 9. ENTRY INTO A HEXAGONAL NETWORK

Original firms are shown by circled crosses. Firms that enter on the first, second, and third rounds of entry are shown by the dots, triangles, and squares, respectively. Market areas are not shown. The lines are solely for visual aid: the original firms surrounding the one at the origin are linked by a solid line; each set of six first-round-entry firms that cluster around each original firm is indicated by a dashed line.

is a counterexample which disproves the conjecture (made by many readers of earlier versions of this paper) that our results are dependent upon our assumptions (e) and (f).

We assume that all customers have identical demand functions of the form

$$q = \exp\left[-P_d\right]$$

where $q$ is quantity demanded and $P_d$ is delivered price. For simplicity, we let transport costs be 1 per unit of distance. Delivered price at any point $(X, Y)$ is then

$$P_d = P + \left[(X - X_0)^2 + (Y - Y_0)^2\right]^{1/2}$$

where $(X_0, Y_0)$ is the location of the firm and $P$ the firm's mill price.

We adopt the conjectural variations with respect to price which is implicit in Mills and Lav and explicit in Beckmann (1971). Any firm $X$ in choosing its price assumes that all neighboring firms will charge the same price that $X$ chooses. The firm maximizes expected profits with respect to price at any given location.

This price-conjectural variation implies that, just as in the model of Section I, the firm's anticipated market boundary will be composed of linear segments which are the perpendicular bisectors of the lines through the firm's own location and the locations of its neighboring firms. The firm's an-

ticipated market area is independent of its price.

The firm's aggregated demand function will be

$$Q = \iint_{MA} \exp\left[-(P + ((X - X_0)^2 + (Y - Y_0)^2)^{1/2}\right]dxdy$$
$$= \exp[-P] \iint_{MA} \exp\left[-((X - X_0)^2 + (Y - Y_0)^2)^{1/2}\right]dxdy$$

The integration is over all points $(X, Y)$ within the firm's anticipated market area, $MA$. This aggregated demand function will have the form

$$Q = M \exp[-P]$$

where $M$ is dependent upon the firm's market area. With zero marginal costs of production, profit maximization at any location requires that the firm find the point of unit elasticity on its aggregated demand function. The point of unit elasticity occurs at a price of 1, and the firm's expectations with respect to its neighbor's price will be correct given that all firms pursue the same profit-maximizing behavior with the same price-conjectural variation.

All other assumptions of Section I are maintained. We analyze the firm's profit-maximizing behavior in this modified model using numerical techniques which are analogous to those described in Section I. At each point, we numerically evaluate the aggregated demand function. We ask the same questions of the revised model as were asked of the model in Section I. The numbers in parentheses in Figures 1–5 show data for this new model analogous to the data already referred to for the model in Section I. Since in this model Market Area $\neq Q \neq TR =$ Gross Profit, we must choose which of these variables to plot. The relevant variable is total revenue, which is the same as gross profits (since Marginal Cost$=0$). In Figure 1, for example, the firm at the origin earns gross profits of 229 in our present model and of 692 in the model of Section I. In both cases, the firm does not wish to locate at the origin (it can earn 230 in the present model and 698 in the model of Section I at the points of maximum profits). In Figures 2 through 5, location at the origin does maximize profits. Since location of the $n$th firm at the origin completes the configuration in each case, we conclude that, just as with the model in Section I, equilateral triangles are not an equilibrium configuration, while configurations of squares and rectangles appear to be equilibrium configurations, as do configurations of regular and irregular hexagons.

Next, we consider entry (on the assumption that profits are large enough to induce it). Using the entry dynamic described in Section I, we discover that rectangles beget rectangles in one round of entry. In both the square and regular hexagonal networks (see Figures 6 and 8) one round of entry does not reproduce the configuration and there is therefore a tendency for these configurations to break up. These results are the same as those for the first round of entry in the model of Section I.[13]

### III. Conclusions

(1) There is a wide range of configurations of firms—including squares, rectangles, regular and irregular hexagons, but not equilateral triangles—that satisfy the equilibrium condition of our models

[13] In subsequent work we have discovered that the best entry point varies with the elasticity of demand. Our results apply as long as elasticity is less than some critical value which varies with the parameters of the model. Above one critical value, rectangles do not reproduce themselves, while above another (very large) critical value, hexagons do reproduce themselves. These relationships are the subject of further research and the results will be published in study papers from the University of British Columbia and Queen's University under the title "Entry Experiments in Löschian Space."

with respect to the location of firms already in the market.

(2) Any of the configurations that satisfy the equilibrium condition for the location of firms already in the market can be made to satisfy the equilibrium conditions for free entry by packing the existing firms densely enough so that the expected profits of a new entrant are negative and loosely enough so that the profits of existing firms are nonnegative.

(3) Zero profits is not a condition of entry equilibrium in our model and thus there is a wide range of density of packing of firms in each of the configurations mentioned in conclusion (1) above that is consistent with entry equilibrium.

(4) On the dynamic assumption about entry that we have investigated, there is no tendency for entry to convert a nonhexagonal configuration into a hexagonal one; indeed a rectangular configuration is more likely to persist through rounds of entry of new firms than is a hexagonal configuration.

(5) The model used to establish conclusions (1), (2), (3), and (4) assumes zero elasticity of demand and an exogenously imposed parametric price. In Section II we demonstrated that none of these conclusions is critically dependent upon these two assumptions. In that section each customer has a downward-sloping demand curve and firms maximize with respect to both price and location. Conclusions (1) through (4) continue to hold.

Given that our results differ from those in the existing literature, we must ask why these differences arise. The basic reasons seem to be methodological.[14] Lösch and many of the location theorists who followed him did not make explicit conjectural-variation assumptions concerning either or both location and price (see, for example, Lösch, pp. 94–97). It is impossible, however, to know what profits a firm expects to earn in alternative locations unless we know what reaction it expects its neighbors to make to changes in its location and price. Therefore, in the absence of conjectural-variation assumptions, equilibrium is undefined and equilibrium conditions cannot be derived.

Not having well-defined equilibrium conditions, many location theorists beginning with Lösch (see pp. 94–97) have imposed what to them seemed to be reasonable equilibrium conditions. We may consider by way of illustration two of the commonly assumed conditions of zero profits and densest packing.[15]

The zero-profits condition is imposed on the argument that as long as the profits of existing firms are positive, it will pay new firms to enter. But this argument assumes that the expected profits of a new entrant, $R^e$, are the same as the actual profits of a typical existing firm, $R^a$ (any existing firm will do as long as they have identical market areas). But Beckmann has shown (1968, p. 44) that there is a class of models for which $R^e(h_0) < R^a(h_0)$ so that for $R^e(h_0) = 0$ it is not necessary that $R^a(h_0) = 0$ (where $h_0$ is any specific density of packing).[16]

The assumed equilibrium condition of densest packing gives rise to the assumption that a regular hexagonal lattice is the

[14] See our (1972b) paper for a much more detailed discussion of this problem than is given here.

[15] For examples two recent articles, Kenneth Denike and John Parr, and John Hartwick, impose both zero profits and densest packing as conditions of equilibrium without deriving them from behavioral assumptions.

[16] Another commonly used argument is that if existing firms are making positive pure profits, a new firm could enter right alongside the old firm, slightly undercut its price, and drive the old firm out of business getting *all* of its profits. If firms make a *ZCV* assumption with respect to existing firms' prices and each new entrant undercuts the existing firm by a small but finite amount, price will eventually be driven down to the point at which profits are zero. Consideration of this frequently employed argument, which employs a price-conjectural variation different from the one used in Section II, is beyond the scope of this paper but our refutation of it can be found in our (1975b) paper.

unique equilibrium configuration. The argument would appear to run as follows: if firms are arranged in another configuration (say, rectangles), and just packed densely enough, i.e., a value of $h$ chosen, so that $R^a(h)=0$, they could all increase their profits by rearranging themselves into a hexagonal lattice. It is clear that if a rectangular configuration prevailed, all firms could increase their profits by agreeing collectively to rearrange themselves into a hexagonal configuration. It is equally clear from our models, however, that when each firm makes atomistic decisions based on conjectural variations with respect to other firms' locations and/or prices, there is no behavioral mechanism that will *necessarily* convert other configurations into hexagons (indeed we find it difficult to conceive of any behavioral mechanism suitable for atomistic decision taking that would be *sufficient* to do the job). Densest packing is not therefore an equilibrium condition of our models.

It seems to us, therefore, that many of the classic propositions of Löschian and post-Löschian location theory are suitable for analyzing optimal rules for collective decisions of a central-planning type, but are quite unsuitable for analyzing the outcome of decentralized decision making that is based on explicit conjectural-variation assumptions and that acts through the market mechanism.

# Input Choices and Uncertain Demand

By Duncan M. Holthausen*

The theory of the firm under demand uncertainty has to date assumed that the firm's input decisions are unaffected by the stochastic nature of demand.[1] This assumption is not usually made explicitly, but it is implied by the assumption that the firm's cost function, presumably derived by finding the minimum cost combination of inputs for any given level of output, is unaffected by the uncertainty. However, if firms must choose some of their inputs before the uncertainty regarding demand is resolved, then different input decisions may involve different levels of risk. Since firms' decisions regarding price and output are affected by demand uncertainty and non-linear risk preferences, as previous authors have shown, it seems reasonable to suspect that their input decisions will also be affected. But if input decisions are affected, then firms' cost functions are not invariant to uncertainty, and the results of previous studies must be reexamined.

Three different types of firms are considered in this paper: the competitive firm, the quantity-setting imperfect competitor, and the price-setting imperfect competitor. Input decisions of the competitive firm and the quantity-setting imperfect competitor are shown to be unaffected by demand uncertainty, and hence the assumption of an unchanging cost function is appropriate in these cases. For the price-setting imperfect competitor, however, input decisions are influenced by demand uncertainty, and an unchanging cost function is therefore not appropriate. This case is considered in some detail, and conditions under which results can differ from those previously reported in the literature are examined.

## I. Random Demand and Timing of Input Decisions

Following Leland, the implicit demand relationship

$$f(p, q, u) = 0 \tag{1}$$

is assumed to contain a random element $u$, which is not known *ex ante*, but has subjective probability density $dF(u)$. It is assumed that for any $u$, $p$ and $q$ are inversely related, and that larger values of $u$ are associated with greater demand.

Assuming $f$ to have continuous partial derivatives, (1) can be solved for either $p$ or $q$:

$$\begin{aligned} &p = p(q, u) \\ &\partial p(q, u)/\partial q < 0, \quad \partial p(q, u)/\partial u > 0 \end{aligned} \tag{2}$$

$$\begin{aligned} &q = q(p, u) \\ &\partial q(p, u)/\partial p < 0, \quad \partial q(p, u)/\partial u > 0 \end{aligned} \tag{3}$$

In both cases, the firm's revenue function is assumed to be concave.[2] For the perfectly competitive firm, relation (2) becomes simply

$$\begin{aligned} &p = p(u) \\ &\partial p(u)/\partial u > 0 \end{aligned} \tag{4}$$

and relation (3) does not exist.

The firm is assumed to produce its single output $q$ subject to the production function

* Assistant professor of business administration, The Amos Tuck School of Business Administration, Dartmouth College. This work was supported by a Tuck Associates research grant.

[1] See Hayne Leland, David Baron (1970, 1971), and Agnar Sandmo for recent work in this area.

[2] Specifically, $p(q,u)q$ is assumed concave in $q$, and $q(p,u)p$ is assumed concave in $p$.

$$(5) \qquad q = Q(K, L)$$

which gives output as a function of the two inputs, capital stock ($K$) and labor ($L$). The usual assumptions of positive marginal products $\partial Q/\partial L > 0$ and $\partial Q/\partial K > 0$ and diminishing returns $\partial^2 Q/\partial L^2 < 0$ and $\partial^2 Q/\partial K^2 < 0$ are also made. An important consideration is the firm's timing of input decisions. For the purposes of this paper, it is assumed that the level of capital stock must be decided before $u$ is known, and therefore before the actual level of demand is known. Thus capital stock is an *ex ante* control. Labor, on the other hand, is considered more flexible and may be adjusted after $u$ is known. Hence labor is an *ex post* control.

To reinforce this notion and to simplify the following analysis, the production function in (5) is solved for labor to give the labor-requirements function

$$(6) \qquad L = \mathcal{L}(q, K)$$

where $\mathcal{L}(q, K)$ gives the amount of labor necessary to produce output $q$ with capital stock $K$. This formulation emphasizes the assumption that labor is flexible and can be used to satisfy any level of demand. In fact, once the levels of $q$ and $K$ are determined, it is assumed that the firm's use of labor is determined by the labor-requirements function. Hence, labor is not considered a decision variable in the models that follow.

The signs of the first partial derivatives $\partial\mathcal{L}(q, K)/\partial q > 0$ and $\partial\mathcal{L}(q, K)/\partial K < 0$ follow from the assumption of positive marginal products for $K$ and $L$. The economic meaning of the first condition is that an increase in output (with capital stock held constant) can only be achieved by increasing labor, and the second condition implies that capital and labor can be substituted for each other to produce a given output.

In addition, $\partial^2\mathcal{L}(q, K)/\partial q^2 > 0$ follows from the assumption of diminishing returns to labor. In other words, with capital held constant, increasingly larger amounts of labor are required to produce each succeeding unit of output. It is also assumed that the isoquants of the production function are convex and therefore $\partial^2\mathcal{L}(q, K)/\partial K^2 > 0$. This condition is simply the usual one that as capital is substituted for labor in the production of a constant output, increasingly larger amounts of capital are required to replace each succeeding unit of labor. Or put another way, the marginal rate of technical substitution between capital and labor becomes larger (less negative) as more capital is used to produce a given output. Finally, the labor-requirements function is assumed to be convex in $q$ and $K$.[3]

## II. Optimal Input Choices for the Competitive Firm and the Quantity-Setting Imperfect Competitor

The firm's problem is taken to be the maximization of its expected utility of profit

$$(7) \qquad \underset{q,K}{\text{Maximize}}\ EU(\Pi)$$

where $U$ is a von Neumann-Morgenstern utility function with profit $\Pi$ its argument.

It is assumed that the firm purchases its inputs in perfectly competitive markets at constant prices, $w$ for labor and $c$ for capital. The firm's cost of capital (i.e., its opportunity cost for resources tied up in capital stock) is denoted $i$. Hence, profit is given by

$$(8) \quad \Pi = p(q, u)q - w\mathcal{L}(q, K) - icK$$

where $p(q, u) = p(u)$ for the perfect competitor.

The first-order conditions for (7) are

$$(9) \quad E\{[p(q, u) + q[\partial p(q, u)/\partial q] - w[\partial\mathcal{L}(q, K)/\partial q]]U'(\Pi)\} = 0$$

$$(10) \quad E\{[-w[\partial\mathcal{L}(q, K)/\partial K] - ic]U'(\Pi)\} = 0$$

[3] Note that although $\partial^2\mathcal{L}(q, K)/\partial q^2$ and $\partial^2\mathcal{L}(q, K)/\partial K^2$ are both positive, this is not enough to guarantee that $\mathcal{L}(q, K)$ is convex.

where $U'(\Pi)=dU(\Pi)/d\Pi>0$. Under the assumption that $p(q, u)q$ is concave and $\mathcal{L}(q, K)$ is convex, $\Pi$ is a concave function, and thus any point satisfying the first-order conditions provides a maximum for the problem as long as $U$ is linear or concave.[4]

It is important to notice that for the perfect competitor and the quantity-setting firm, both $q$ and $K$ are *ex ante* controls. That is, the firm sets the quantity to be produced and the amount of capital to be used before it knows the actual level of demand (i.e., before $u$ is known). Once $u$ is revealed, and assuming it sells all the $q$ it produces, the firm can charge any $p$ up to and including $\bar{p}=p(\bar{u}, \bar{q})$ where the bars denote the revealed value of $u$ and the setting of $q$. Being rational, the firm will set $\bar{p}$.

Since the firm sets both $q$ and $K$ *ex ante*, the amount of labor required, given by $L=\mathcal{L}(q, K)$, is known before $u$ is revealed. Thus $\mathcal{L}(q, K)$ is not stochastic, and (10) may be written as

$$(11) \quad [-w[\partial\mathcal{L}(q, K)/\partial K] - ic]EU'(\Pi) = 0$$

or

$$(12) \quad -\partial\mathcal{L}(q, K)/\partial K = \frac{ic}{w}$$

But (12) is just the deterministic rule for cost minimization. The firm employs capital and labor in such amounts that the marginal rate of substitution between inputs equals the ratio of their prices. Thus, the quantity-setting firm uses the least cost combination of capital and labor to produce the level of output it chooses. This should appear eminently reasonable, since the firm selects its level of output before the random element of demand $u$ is known. Thus $q$ is known for certain *ex ante*, and the firm may choose the level of $K$ (and hence $L$) which minimizes production cost.

It should be noted that although the quantity-setting firm facing stochastic demand uses the deterministic rule for cost minimization, it does not necessarily use the same levels of capital and labor as the firm operating under certainty does. As Leland, Baron (1970, 1971), and Sandmo have all shown, the perfect competitor or quantity setter facing uncertain demand will produce more or less than the firm under certainty depending on its risk preferences. Thus, the firm facing stochastic demand will generally use different amounts of capital and labor than an identical firm with certain demand.

Since the firm will always minimize costs for the level of output chosen, however, the assumption that the firm's cost function is unaffected by the presence of demand uncertainty is appropriate. Condition (9) may be analyzed to obtain results similar to those of Baron (1970), Leland, and Sandmo.

## III. Optimal Input Choices for the Price-Setting Imperfect Competitor

In the case of the price setter, the firm's problem is to

$$(13) \quad \underset{p,K}{\text{Maximize}}\ EU(\Pi)$$

where

$$(14) \quad \Pi = q(p, u)p - w\mathcal{L}(q(p, u), K) - icK$$

Writing $\mathcal{L}(q(p, u), K)$ as $\mathcal{L}(q, K)$ for notational convenience, the first-order conditions for (13) are

$$(15) \quad E\{[q(p, u) + p[\partial q(p, u)/\partial p] - w[\partial\mathcal{L}(q, K)/\partial q] \cdot [\partial q(p, u)/\partial p]]U'(\Pi)\} = 0$$

$$(16) \quad E\{[-w[\partial\mathcal{L}(q, K)/\partial K] - ic]U'(\Pi)\} = 0$$

In this case, $p$ and $K$ are the firm's *ex ante* controls. The firm chooses its price and amount of capital before the level of

[4] The revenue function $p(u)q$ for the competitive firm, is linear, but $\Pi$ is still concave because of the production function assumptions.

demand is known. Once the uncertain element $u$ of demand is realized, the firm produces the $q$ implied by $\bar{q}=q(\bar{u}, \bar{p})$, where the bars represent the realization of $u$ and the setting of $p$. Although the firm might decide to produce and sell less than $\bar{q}$, this would be rational only if the marginal cost of production at $\bar{q}$ exceeded the price $\bar{p}$. To rule out this possibility, it is assumed that price is greater than the marginal cost of production, i.e., $\bar{p}>w[\partial\mathcal{L}(\bar{q}, \bar{K})/\partial q]$, for the chosen values of $p$ and $K$ and the realized value of $u$.

Using the fact that for two random variables $X$ and $Y$, $E(XY)=E(X)E(Y)+cov\,(X, Y)$, equation (16) may be written as

$$(17)\quad E\{-w[\partial\mathcal{L}(q, K)/\partial K] - ic\}EU'(\Pi) + w\,cov\,[-\partial\mathcal{L}(q, K)/\partial K, U'(\Pi)] = 0$$

or

$$(18)\quad E[-\partial\mathcal{L}(q, K)/\partial K] = \frac{ic}{w} - \frac{cov\,[-\partial\mathcal{L}(q, K)/\partial K, U'(\Pi)]}{EU'(\Pi)}$$

In this case, the firm departs from the expected cost minimizing strategy as long as the covariance term is nonzero. A sufficient condition for the covariance term to be zero is that the firm's utility be linear in profits, i.e., that the firm be risk neutral. In this case, $U'(\Pi)$ is constant and the covariance must be zero. The risk-neutral firm, therefore, sets its expected marginal rate of technical substitution equal to the slope of its isocost line and thereby minimizes expected cost.

Firms with non-linear risk preferences will depart from this expected cost minimizing strategy and hence will be in effect operating with a different cost function than the risk neutral firm. To determine the direction of the effect of risk preferences, the sign of the covariance term must be determined. It is shown in the next section that this depends on the normality of capital and on the profitability of increased output with price held fixed.

## IV. Risk Preferences and Departures from Minimum Cost for Price-Setting Firms

The sign of the covariance term in (18) can be determined by examining the changes in $-\partial\mathcal{L}(q, K)/\partial K$ and $U'(\Pi)$ as $u$ changes. This requires that we be able to sign the terms

$$(19)\quad \partial U'(\Pi)/\partial u = [\partial\Pi/\partial u]U''(\Pi) = [p - w[\partial\mathcal{L}(q, K)/\partial q]][\partial q(p, u)/\partial u]U''(\Pi)$$

and

$$(20)\quad \partial[-\partial\mathcal{L}(q, K)/\partial K]/\partial u = -[\partial^2\mathcal{L}(q, K)/\partial q\partial K][\partial q(p, u)/\partial u]$$

As shown in the Appendix, under the assumption that price exceeds the marginal cost of producing additional units, $\partial\Pi/\partial u$ is positive and hence the sign of (19) is the same as the sign of $U''(\Pi)$. Also, if capital is a normal input (which would usually be the case), then the sign of (20) is positive. Hence under these assumptions it follows that

$$(21)\quad cov\,[-\partial\mathcal{L}(q, K)/\partial K, U'(\Pi)] \begin{cases} >0 & \text{for } U \text{ convex} \\ =0 & \text{for } U \text{ linear} \\ <0 & \text{for } U \text{ concave} \end{cases}$$

Applying (21) to equation (18) yields

$$(22)\quad E[-\partial\mathcal{L}(q, K)/\partial K] \begin{cases} <\dfrac{ic}{w} & \text{for } U \text{ convex} \\ =\dfrac{ic}{w} & \text{for } U \text{ linear} \\ >\dfrac{ic}{w} & \text{for } U \text{ concave} \end{cases}$$

It follows that risk-preferring firms ($U$ convex) use a greater amount of capital than that which minimizes expected cost for the level of output produced while risk-averse ($U$ concave) firms use a smaller amount of capital than the expected cost

minimizing amount for the level of output produced.[5]

In terms of a cost function such as $c(q)+F$ where $c(q)$ represents variable cost and $F$ fixed cost, both $c(q)$ and $F$ will be affected. The risk-preferring firm will use a higher level of fixed cost than the risk-averse firm, since its capital stock is large relative to its output, while the risk-averse firm's capital stock is small relative to output. On the other hand, the risk-averse firm will require relatively more labor than the risk-preferring firm, and so its variable costs will be higher. Thus, the assumption that the firm's cost function is unaffected by demand uncertainty and risk preferences is incorrect.

The finding that the risk-averse firm uses a production process with low fixed costs and high variable costs while the risk-preferring firm uses a high fixed cost, low variable cost process is intuitively appealing. The low fixed cost, high variable cost process used by the risk-averse firm gives it a low break-even point, and keeps its losses small should demand turn out to be less than expected. Doing this, of course, does reduce the profit that the firm can make if demand is high, because it will have to use an inefficiently low capital-labor ratio in that case.[6] These are the kinds of tradeoffs typical of risk-averse behavior; the firm gives up the possibility of large profits to insure against large losses.

The risk-preferring firm, on the other hand, uses a higher degree of leverage than either the risk-neutral or risk-averse firm. By using a high fixed cost production process, it incurs large losses if demand is low, but reaps large profits if demand is greater than expected.

## V. The Effect of Increasing Risk Aversion on the Optimal Level of Capital Stock for Price-Setting Firms

The results of Section IV can be generalized for the case of the risk-averse firm by showing that for a given price the firm will reduce its optimal level of capital stock as aversion to risk increases. The degree of risk aversion will be measured by the Pratt-Arrow index, which is defined as

$$r(\Pi) = -\frac{U''(\Pi)}{U'(\Pi)} \tag{23}$$

This measure of risk aversion is always positive for a risk-averse firm since $U''(\Pi)<0$. Defining the concept of "increasing risk aversion" to mean that the firm would be willing to pay an increasing amount to insure against a given risk, John Pratt has shown that the index $r(\Pi)$ increases as the utility function becomes more risk averse.

Using this measure of risk aversion, it is now shown that with price held fixed, the more risk averse a firm becomes, the less capital stock it will use. Consider two firms with concave utility functions $U_1(\Pi)$ and $U_2(\Pi)$ with $r_1(\Pi)>r_2(\Pi)>0$ for all $\Pi$, where $r_1$ and $r_2$ are the Pratt-Arrow indexes of risk aversion for $U_1$ and $U_2$, respectively. If price is fixed at the same level for both firms, firm one's first-order condition is given by

$$\int_{-\infty}^{\infty}\{[-w[\partial\mathcal{L}(q, K_1^*)/\partial K] - ic]U_1'(\Pi)\}\,dF(u) = 0 \tag{24}$$

where $dF(u)$ is the subjective probability density of the random element of demand,

[5] Again, it should be noted that the level of output produced by firms with non-linear risk preferences will usually differ from that produced by risk-neutral firms or firms operating in a deterministic world. This topic is treated in Sections VI and VII.

[6] It may be noted in passing that since risk-averse price-setting firms have been shown to undercapitalize on average, and since regulated firms are characterized by price-setting behavior, the Averch-Johnson overcapitalization bias that accompanies rate-of-return regulation may be beneficial if regulated firms are risk averse. See my unpublished paper for further elaboration of this point.

and $K_1^*$ is firm one's optimal level of capital stock. As shown in the Appendix, $-\partial \mathcal{L}(q, K)/\partial K$ is increasing in $u$ if capital is a normal input. Thus, $-w[\partial \mathcal{L}(q, K_1^*)/\partial K]-ic$ could be negative for small $u$ and positive for large $u$. Define $u^0$ as the value of $u$ for which $-w[\partial \mathcal{L}(q, K_1^*)/\partial K]-ic=0$. Then $-w[\partial \mathcal{L}(q, K_1^*)/\partial K]-ic$ will be negative for $u<u^0$ and positive for $u>u^0$. Also define $\Pi^0$ as the value of $\Pi$ when $u=u^0$.

Partitioning (24) into two parts and dividing by the constant $U_1'(\Pi^0)$, the firm's first-order condition may be written as

$$(25)\quad \int_{-\infty}^{u^0} \frac{U_1'(\Pi)}{U_1'(\Pi^0)}[-w[\partial \mathcal{L}(q, K_1^*)/\partial K] - ic]dF(u) + \int_{u^0}^{\infty} \frac{U_1'(\Pi)}{U_1'(\Pi^0)}[-w[\partial \mathcal{L}(q, K_1^*)/\partial K] - ic]dF(u) = 0$$

Now evaluate firm two's first-order condition at the optimal point for firm one (i.e., at $K_1^*$) and divide this condition by the constant $U_2'(\Pi^0)$ to obtain

$$(26)\quad \int_{-\infty}^{u^0} \frac{U_2'(\Pi)}{U_2'(\Pi^0)}[-w[\partial \mathcal{L}(q, K_1^*)/\partial K] - ic]dF(u) + \int_{u^0}^{\infty} \frac{U_2'(\Pi)}{U_2'(\Pi^0)}[-w[\partial \mathcal{L}(q, K_1^*)/\partial K] - ic]dF(u)$$

Subtracting (25) from (26) yields

$$(27)\quad \int_{-\infty}^{u^0}\left[\frac{U_2'(\Pi)}{U_2'(\Pi^0)} - \frac{U_1'(\Pi)}{U_1'(\Pi^0)}\right]\cdot[-w[\partial \mathcal{L}(q, K_1^*)/\partial K] - ic]dF(u) + \int_{u^0}^{\infty}\left[\frac{U_2'(\Pi)}{U_2'(\Pi^0)} - \frac{U_1'(\Pi)}{U_1'(\Pi^0)}\right]\cdot[-w[\partial \mathcal{L}(q, K_1^*)/\partial K] - ic]dF(u)$$

One of Pratt's results is required at this point. Pratt's Theorem 1 shows, among other things, that if $U_1(\Pi)$ is more risk averse than $U_2(\Pi)$ in the sense that $r_1(\Pi)\geq r_2(\Pi)$ for all $\Pi$ [and $>$ for at least one $\Pi$], then[7]

$$\frac{U_1'(x)}{U_1'(w)} \leq [<] \frac{U_2'(x)}{U_2'(w)} \qquad \text{for } w < x$$

As shown in the Appendix, $\Pi$ is increasing in $u$ as long as price exceeds marginal cost, and thus $\Pi\leq\Pi^0$ for $u\epsilon(-\infty, u^0)$ and $\Pi\geq\Pi^0$ for $u\epsilon(u^0, \infty)$. Therefore, the first term in brackets in (27) is negative by Pratt's equation 20, and the second term in brackets is negative by definition of $u^0$. Hence, the first integral in (27) is positive. The second integral in (27) is also positive, since the first term in brackets is positive by Pratt's equation 20, and the second term is positive by definition of $u^0$. Hence, (27) is positive, which implies (26) is also positive. But (26) is the first-order condition for firm two evaluated at $K_1^*$. Under the concavity assumptions made earlier, $K$ must be increased above $K_1^*$ to drive (26) to zero. Thus, it follows that $K_2^*>K_1^*$. The more risk-averse firm (firm one) uses less capital.

Hence, with price held fixed, the amount of capital stock used decreases as risk aversion increases. Thus, the more risk-averse firm will use more labor to produce any given level of output and hence will use a lower capital-labor ratio. Since a risk-neutral firm uses the efficient ratio, any risk-averse firm will undercapitalize as noted before.

Under the hypothesis of decreasing absolute risk aversion, it follows that the risk-averse firm's capital-labor ratio increases as its wealth increases. Loosely interpreted, this implies that the larger the risk-averse firm becomes, the closer to the efficient capital-labor ratio it will operate. Hence, one might expect larger firms to

[7] See Pratt's equation 20, p. 129.

operate more efficiently than smaller ones, *ceteris paribus*.

### VI. The Effect of Increasing Risk Aversion on the Optimal Price for Price-Setting Firms

Results similar to those of Leland can be obtained from this model if it is assumed that capital stock is held constant as the level of risk aversion varies. Holding $K$ fixed at, say, $\overline{K}$ is equivalent to assuming the cost function is invariant with changes in risk aversion, since the total cost function will be $w\mathcal{L}(q, \overline{K})+ic\overline{K}$ which is of the form $c(q)+F$. Using a method of analysis similar to that in Section V, it can be shown that if $K$ is fixed, then as aversion to risk increases, price decreases (increases) (is constant) as $\partial(\partial\Pi/\partial p)/\partial u>0$ $(<0)(=0)$. It follows, therefore, that the risk-averse firm sets its price below the risk-neutral firm if $\partial(\partial\Pi/\partial p)/\partial u>0$, above if $\partial(\partial\Pi/\partial p)/\partial u<0$, and equal to the risk-neutral firm if $\partial(\partial\Pi/\partial p)/\partial u=0$.

The sign of $\partial(\partial\Pi/\partial p)/\partial u$ cannot be determined unambiguously a priori. For simple demand functions, its sign is usually positive. For example, it is positive if $u$ appears only as an additive shift variable. However, in general its sign is ambiguous. Thus the effect of uncertainty on the price charged by the risk-averse price setter (with capital stock fixed) is ambiguous. It depends critically on how changes in uncertainty affect the profitability of price changes as Leland has shown.

### VII. Simultaneous Effects on Price and Capital Stock

Examining the effects of uncertainty on capital and price separately may give some insight into the problem, but a complete analysis requires simultaneous treatment of capital and price. As is often the case in economics, such treatment is not entirely satisfactory, but it does indicate that the earlier results on price given in Section VI are not complete as they stand. Allowing the firm to make both input and price decisions simultaneously changes its pricing decision in some cases.

It is necessary to introduce a bit more notation at this point. Let $\phi\equiv EU(\Pi)$. Then $\phi_p=\partial EU(\Pi)/\partial p$, $\phi_{pK}=\partial^2 EU(\Pi)/\partial p\partial K$, and so on. Also, let $r$ be the Pratt-Arrow index of risk aversion, so that, for example, $dp/dr$ measures the change in price that occurs with a change in risk aversion.

We are interested in the changes in price and capital that accompany changes in risk aversion, so the signs of $dp/dr$ and $dK/dr$ are of interest. The relevant comparative statics experiment may be expressed as

$$\text{(28)}\qquad \begin{bmatrix}\phi_{pp} & \phi_{pK}\\ \phi_{pK} & \phi_{KK}\end{bmatrix}\begin{bmatrix}dp/dr\\ dK/dr\end{bmatrix} = -\begin{bmatrix}\phi_{pr}\\ \phi_{Kr}\end{bmatrix}$$

In Section V it was shown that under certain reasonable conditions when price is fixed, the level of capital stock declines as risk aversion increases. Hence $dK/dr\,|_{p\text{ constant}}<0$. Taking the total differential of the first-order condition $\phi_K=0$, we have (for $p$ fixed)

$$\text{(29)}\qquad \phi_{KK}dK + \phi_{Kr}dr = 0$$

Therefore,

$$\text{(30)}\qquad dK/dr\,|_{p\text{ constant}} = -\frac{\phi_{Kr}}{\phi_{KK}}$$

Since $dK/dr\,|_{p\text{ constant}}<0$ and $\phi_{KK}<0$ by second-order conditions, it follows that $\phi_{Kr}<0$. Likewise, it can easily be shown that $\phi_{pr}\lesseqgtr 0$ as $\partial(\partial\Pi/\partial p)/\partial u\gtreqless 0$.

The only other sign required to carry out the comparative statics experiment is that of $\phi_{pK}\equiv\partial^2 EU(\Pi)/\partial p\partial K$, which may be written

$$\begin{aligned}\text{(31)}\qquad \phi_{pK} = E\{&-w[\partial^2\mathcal{L}(q, K)/\partial q\partial K]\\ &\cdot[\partial q(p, u)/\partial p]U'(\Pi)\\ &+[-w[\partial\mathcal{L}(q, K)/\partial K] - ic]\\ &\cdot[\partial\Pi/\partial p]U''(\Pi)\}\end{aligned}$$

As shown in the Appendix, $\partial^2 \mathcal{L}(q, K)/\partial q \partial K < 0$ as long as capital is a normal input. Since $\partial q(p, u)/\partial p < 0$ and $U'(\Pi) > 0$ by assumption, the first term in (31) is negative. If the firm is risk neutral, $U''(\Pi) = 0$ and $\phi_{pK}$ is always negative. For a risk-averse firm $U''(\Pi) < 0$, but the signs of $[-w[\partial \mathcal{L}(q, K)/\partial K] - ic]$ and $\partial \Pi/\partial p$ are ambiguous. It would seem reasonable to assume, however, that for small degrees of risk aversion ($U''(\Pi)$ close to zero), $\phi_{pK}$ would still be negative, although as risk aversion increases we cannot rule out the possibility that $\phi_{pK}$ becomes positive. The assumption $\phi_{pK} < 0$ will be used in what follows, but its tenuous nature should be remembered.

Now solve (28) for $dp/dr$ and $dK/dr$ as follows.

$$(32) \qquad dp/dr = \frac{-\phi_{pr} - \phi_{pK}(dK/dr)}{\phi_{pp}}$$

$$(33) \qquad dK/dr = \frac{\phi_{pK}\phi_{pr} - \phi_{Kr}\phi_{pp}}{\phi_{pp}\phi_{KK} - \phi_{pK}^2}$$

The denominator of (33) is positive by second-order conditions. The second term in the numerator is negative since $\phi_{Kr} < 0$ as shown above and $\phi_{pp} < 0$ by second-order conditions. If $\partial(\partial \Pi/\partial p)/\partial u \leq 0$, then $\phi_{pr} \geq 0$ as shown above, and under the assumption $\phi_{pK} < 0$, it follows that $dK/dr < 0$. Using this in (32), it follows that $dp/dr > 0$. If $\partial(\partial \Pi/\partial p)/\partial u > 0$, then $\phi_{pr} < 0$ and the sign of $dK/dr$ is ambiguous. In this case, we cannot have both $dK/dr > 0$ and $dp/dr > 0$, but any other pair of signs is acceptable.

These results are generally consistent with the nonsimultaneous results reported earlier in this paper. For example, if $\partial(\partial \Pi/\partial p)/\partial u < 0$, then $dK/dr < 0$ and $dp/dr < 0$. The risk-averse firm uses less capital and sets a higher price as risk aversion increases. In particular, it uses less capital and a higher price than a risk-neutral firm. These results are identical to those presented in Sections V and VI.

If the profitability of a price increase is unaffected by uncertainty (i.e., $\partial(\partial \Pi/\partial p)/\partial u = 0$), the simultaneous result is $dK/dr < 0$ and $dp/dr > 0$. However, in this case, the result differs from the earlier finding that $dp/dr = 0$. In this instance, then, considering pricing and input decisions simultaneously is important. The risk-averse firm will use less capital than the risk-neutral firm and will set a higher price. Leland's model and the analysis presented in Section VI of this paper both assume that the firm's input decisions are not affected by uncertainty, and both lead to the conclusion that if $\partial \Pi/\partial p$ is independent of $u$, the risk-averse firm will set the same price as the risk neutral firm. The simultaneous result shows, however, that the risk-averse firm will adjust its capital stock downward and hence raise its price above the risk neutral price.

Finally, for $\partial(\partial \Pi/\partial p)/\partial u > 0$, the results are ambiguous. We can rule out the possibility that the risk-averse firm will simultaneously increase its capital stock and price above the risk neutral level. Other types of behavior are, however, consistent with the model. For example, the firm could decrease capital stock and increase price as it became more risk averse. Thus, while the nonsimultaneous result implies $dp/dr < 0$, a simultaneous analysis shows that $dp/dr > 0$ cannot be ruled out when capital stock is decreasing in risk aversion.

## VIII. Conclusion

A model of an expected utility maximizing firm facing random demand has been developed. The major difference between this model and earlier models reported in the literature is that the firm is allowed to make input decisions as well as pricing and output decisions.

It was shown that the results of earlier models are correct for the perfectly competitive firm and the quantity-setting im-

perfect competitor. In both of these cases, the firm sets the quantity it is to produce before the random element of demand is known. Hence, quantity is an *ex ante* control, and the firm selects the optimal input combination as it would if there were no uncertainty.

For the price-setting imperfect competitor, however, quantity is an *ex post* control. That is, the quantity to be produced is uncertain at the time some input decisions must be made. Here, the firm's attitude toward risk plays an important role in its behavior. In general, the risk-averse or risk-preferring firm will use a different input mix than the risk-neutral firm. Hence, earlier models which have assumed the firm's cost function to be invariant with changes in risk preference are not complete.

The major findings for the price-setting imperfect competitor are:

1. The risk-averse firm will use an expected capital-labor ratio less than the efficient ratio while a risk-preferring firm will use an expected capital-labor ratio greater than the efficient ratio.
2. If price is fixed, the amount of capital stock used by the risk-averse firm decreases as aversion to risk increases.
3. If capital stock is held fixed, the price charged by the risk-averse firm may decrease, increase, or remain constant depending on how the profitability of a price increase is affected by uncertainty.
4. Considering both price and capital stock decisions simultaneously, some of the earlier results are shown to be incorrect or not complete. The results affected are primarily those dealing with pricing behavior.

In general, then, earlier models of the price-setting firm under demand uncertainty are incomplete because they assume the firm's cost function to be a given. When both prices and inputs are considered simultaneously, some deviations from the results of the earlier models occur, and in some cases, results that had been unambiguous are now not as clear cut.

## Appendix

The sign of (19) depends on the sign of $p-w[\partial\mathfrak{L}(q,K)/\partial q]$, since $\partial q(p,u)/\partial u>0$ and the sign of $U''(\Pi)$ depends on the concavity-convexity of $U$. The term $\partial\mathfrak{L}(q,K)/\partial q$ represents the additional labor required to produce a small increment in output. Hence, $w[\partial\mathfrak{L}(q, K)/\partial q]$ is the marginal cost of producing an increment in output when the amount of capital is fixed. Under the assumption made in Section III, that price is greater than the marginal cost of production (a reasonable condition in most cases), $p-w[\partial\mathfrak{L}(q,K)/\partial q]$ is positive, and the sign of (19) is the same as the sign of $U''(\Pi)$.

The sign of (20) is the same as the sign of $\partial^2\mathfrak{L}(q,K)/\partial q\partial K$, since $\partial q(p,u)/\partial u$ is positive. The sign of $\partial^2\mathfrak{L}(q,K)/\partial q\partial K$ in turn depends on whether capital is a normal or an inferior input. The assumption that capital is a normal input appears to be an entirely reasonable one for most firms and will be used in what follows. Under this assumption, larger amounts of capital would be used as planned output increases.

To sign $\partial^2\mathfrak{L}(q,K)/\partial q\partial K$, we must ask how the marginal rate of substitution between capital and labor $(\partial\mathfrak{L}(q,K)/\partial K)$ behaves in the short run as output increases and capital is held constant. We know, since capital is assumed to be a normal input and input prices are assumed constant, that in the long run capital would be increased as output increases and that $\partial\mathfrak{L}(q,K)/\partial K$ would remain constant, because any optimal point must be a point of tangency with an isocost line whose slope is constant. Therefore, if output is increased and capital is held fixed, the firm will have to operate with less than the desired amount of capital. We know that $\partial\mathfrak{L}(q, K)/\partial K$ will decrease (i.e., become more negative) when capital is reduced because of the assumption of convex isoquants (which im-

plies $\partial^2\mathcal{L}(q, K)/\partial K^2>0$). Hence $\partial\mathcal{L}(q, K)/\partial K$ will be smaller than it would have been had the firm been able to adjust its level of capital stock to the increased level of output. It follows that $\partial^2\mathcal{L}(q, K)/\partial q\partial K<0$, and therefore (20) is positive under the assumption that capital is a normal input.

# The Long-Run Analysis of the Labor-Managed Firm: An Alternative Interpretation

*By* EIRIK G. FURUBOTN*

The pure theory of the labor-managed firm, as developed by Benjamin Ward, Evsey Domar, and Jaroslav Vanek,[1] is based on the assumption that the collective will seek to maximize income per worker. Apart from the emphasis on this special behavioral postulate, however, the analysis runs parallel with conventional micro theory.[2] Clearly, the approach has some advantages. In so far as the firm's objective is taken to be simple "wage" maximization, a straightforward optimization problem can be formulated; and, then, by following familiar technical procedures, it is possible to determine the equilibrium levels of factor usage in the long or short run, the response of the firm to price changes, etc.[3] The question that arises, though, is whether this particular interpretation of the case leads to any significant understanding of the behavior of the labor-managed enterprise. The Ward-Domar-Vanek model may have surface plausibility, but the model's crucial element, the maximand, can certainly be challenged.[4]

Reduced to simplest terms, the argument to be developed here is that an adequate theory of the self-managed firm must consider the preferences and wealth increasing opportunities of those individuals *actually making economic decisions*. At any moment of time, particular individuals are members of the working collective, and it is this constituency that must decide the firm's actions in the next time frame. The precise set of policy alternatives open depends on various factors, including the existing structure of property rights; but whatever the alternatives present, policies will presumably be evaluated in light of their probable consequences for the specific group involved in making the decisions. The worker-voters who actually determine the firm's behavior are not concerned with the position of labor in general, but with their own welfare.

More than semantics is at issue. For realistically a policy that maximizes income per laborer (without regard to the particular workers involved) need not be optimal from the standpoint of the "original" members of the collective. This situation carries direct implications for the theory of the firm; the behavior predicted for the labor-managed enterprise will take one form when the maximand is income per laborer, and an entirely different form when the maximand is the welfare index of a particular group of workers. Existing literature treats the first case. But the second case, which seems much more in harmony with the concept of untrammeled labor management, requires further study and is the concern of the present investigation.

[4] There is no doubt that the choice of the maximand is crucial to the model of the labor-managed firm. See Maurice and Ferguson, pp. 18–19.

## I. Labor-Management and the Collective's Preference Function

The philosophy of labor-management presupposes self-government by the workers and assumes that each firm will be guided by the desires of its employees.[5] This emphasis on freedom from external controls is highly significant; indeed, the labor-managed firm is of special interest to socialist nations precisely because the new organization promises to end the alienation of labor. It follows, of course, that if alienation is to be countered, the firm's policies must always be arrived at through democratic processes in which all current employees take part. The working collective is best understood as a microcosmic society, and the political choices that are made within this society are crucial. That is, the voting process decides control of the firm and ultimately leads to the establishment of the firm's objectives with respect to wages, employment, output, investment, etc. Like other societies, the collective is an ongoing social system and subject to change. Both the characteristics of the collective and the external conditions faced by it will tend to shift over time. Thus, in formulating an optimization model that considers how the labor-managed firm adjusts to economic forces, it is essential to use dynamic analysis and conceive of the equilibration process as an ordered sequence of events.

As a first step, attention can be given to the technological constraints under which the firm operates through time. For convenience, we assume that the firm produces subject to a simple stock-flow function:

$$\begin{aligned} &(1) \qquad & q_t &= f(L_t, K_t) \\ && R_t &= g(K_t) \end{aligned}$$

Here $q_t$ represents the flow of commodity output in any period t, $L_t$ is the contemporaneous flow of labor services, and $K_t$ is the stock of capital equipment actually available for production in period t. The time intervals considered are finite and, by assumption, the physical capital acquired in one period cannot be used in active production until the next period. Finally, the raw material input (or inputs) $R_t$ is indicated in (1) as a factor shadow; thus, the amount used per period is always related to the magnitude of the capital stock in accordance with the stipulations of function $g$.

Given system (1), the firm's initial conditions can be stated as the magnitudes of the labor and capital inputs available to the collective at the first time period studied (t=1). These data ($L_1$, $K_1$) are important because *inter alia* they establish: (i) the specific group of workers that is eligible to vote on the firm's policies for the next period,[6] and (ii) the basic economic position from which the group must commence productive activity. All current members of the collective ($L_1$) are free to vote, but individual differences among workers in respect to such things as risk preference, time preference, length of planning horizon, desire for mobility, etc., must lead to different views on what actions the firm should take. Which view prevails depends on the outcome of the political process that is carried on within the firm. Assuming, however, that a relatively homogeneous majority can be formed in period one, it is this group that determines the policies of the firm for period two.

The workers controlling the firm at any time have incentive to perpetuate their domination of policy and, in such way, preserve the best possible economic and social conditions for themselves. Presum-

[5] Branko Horvat is emphatic about this point, p. 99, pp. 106–07.

[6] Assuming that each worker provides the same (fixed) number of hours of labor service per period, any flow $L_t$ implies a unique corresponding employment level for the firm.

ably, then, the *original majority* (as of t=1) will attempt to retain power; and if this group can coalesce into a permanent interest bloc and sustain itself politically over time, the basis of decision-making behavior by the collective is established. In effect, the firm will be guided by a criterion function reflecting the preferences of the employees forming the successful "original majority." Thus, for purposes of the model, it is possible to write the multiperiod utility index:

$$(2)\quad U = \phi(C_1, C_2, \ldots, C_T, X_{11}, X_{12}, \ldots, X_{1T}, X_{21}, X_{22}, \ldots, X_{2T}, \ldots, X_{s1}, X_{s2}, \ldots, X_{sT})$$

Equation (2) is a type of community welfare function and its derivation poses certain theoretical difficulties. It can be assumed, however, that the majority workers have broadly similar tastes so that there is agreement on: (i) the length of the planning horizon (T); (ii) the general time shape of the disposable income stream that is to be generated for the members of the collective ($C_1, C_2, \ldots, C_T$); and (iii) the economic and social environment that is to be maintained within the firm during the period its planned operations are being carried out ($X_{11}, X_{12}, \ldots, X_{21}, \ldots, X_{s1}, \ldots, X_{sT}$). Given agreement on issues (i)–(iii), a basis for rational policy making does exist.[7] On the practical level, at least, preference aggregation is possible,[8] and a consistent long-run program representing the interests of the original majority can be formulated.

There is no problem in understanding that decision makers will be concerned with the income stream the firm can provide ($C_t$, t=1, 2, ..., T). But, under labor-management, workers will also have interest in and control over the internal environment of the firm at each period to the horizon. Many factors, of course, influence the firm's working atmosphere or environment—including such things as the strictness of labor discipline, the pace of work, the levels of risk assumed, the absolute size of the collective, etc. In (2), forces of this type are indicated by the variables: $X_{kt}$, $k=1, 2, \ldots, s$, t=1, 2, ..., T. It is suggested that there are $s$ distinct dimensions to the firm's environment that can be measured with appropriate indexes. In general, then, the satisfaction level of the original majority $U$ is determined by the magnitudes of the variables $C_t$, $X_{kt}$; and each proposed policy action of the firm is judged as relatively desirable or less desirable, depending on how it influences these variables and the value of the index $U$.

Since the size of the firm can change over time, it is entirely possible that the labor force will expand or contract. From the standpoint of the original majority, however, the decision on an ideal employment program presents some difficulty. Any movement from the initial position $L_1$ must be considered carefully because change in the size of the collective yields simultaneous effects in three quite different areas. For each change, the original majority has to assess the costs and benefits associated with: (i) a *production* effect, (ii) an *environmental* effect, and (iii) a *political* effect. For example, in the case of expansion, the decision makers must estimate not only the physical productivity of any additional labor hired, but the impact the labor increment will have on the firm's working environment and on the firm's internal political structure. The last consideration is particularly important since change in the membership of the collective normally implies some danger to the interests of the original majority. New workers coming into a labor-managed enterprise are not just factors of production but po-

[7] See Roy Radner, pp. 47–53.

[8] A majority voting process can be expected to lead to a determinate solution for the production-investment-employment plan. See Gordon Tullock, p. 257.

tential policy makers as well. Thus, the way is open for a transfer of power; voting patterns can be shifted because of the added workers, and new policy directions established for the firm that are contrary to the desires of the original majority.

As far as the environmental variables are concerned, it is clear that these quality indexes ($X_{kt}$) are necessarily tied to the employment level. Each period, the social-economic conditions to be maintained within the firm are decided by a majority vote of the existing members of the collective. In planning the ideal labor program ($L_2, L_3, \ldots, L_T$), then, the *original majority* must anticipate both the direct effects of "crowding" on the firm's environment and the political consequences of labor change. Relative to the latter, what is needed is a series of estimates showing how a labor force of any given size will vote on the issues represented by the $X_{kt}$ variables. The general situation of the decision makers is easily summarized. Assuming that all of the direct and indirect effects of labor variation can be assessed, any proposed value of $L_t$ ($t=2, 3, \ldots, T$) implies a corresponding value for each environmental variable. Specifically, we can write:

$$X_{kt} = \theta_{kt}(L_t), \qquad L_t \geq L_1 \tag{3}$$
$$k = 1, 2, \ldots, s \quad t = 2, 3, \ldots, T$$

These conversion relations are obviously subjective in nature; they refer to what the initial majority *thinks* will happen as the labor force is expanded to any level in any period. Precisely how the respective translations work out in quantitative terms depends on the psychological attitudes of the decision makers, on the particular estimation procedures employed, and on the initial conditions prevailing in the collective—including the size of the collective in period one and the size of the original majority group. Various outcomes are conceivable, but it seems reasonable to conjecture that the members of the original majority will be relatively cautious and suspicious of change. Any enlargement of the collective tends to make their political control less secure and promises some deterioration of the firm's environment. Thus, an *inverse* relation can be expected to exist between each environmental index $X_{kt}$ and the contemporaneous labor input ($L_t$).

From a formal standpoint, it will be convenient to substitute (3) in (2) and secure a new objective function written in terms of $C_t$ and $L_t$.

$$U = \phi[C_t, \theta_{kt}(L_t)], \quad t = 1, 2, \ldots, T \tag{4}$$
$$k = 1, 2, \ldots, s$$

This version of the utility index makes it easy to understand why there is a general reluctance on the part of the original majority to increase the size of the labor force. By differentiation, we know:

$$\frac{\partial U}{\partial L_t} = \frac{\partial U}{\partial C_t}\frac{\partial C_t}{\partial L_t} + \sum_{k=1}^{s} \frac{\partial U}{\partial X_{kt}}\frac{\partial X_{kt}}{\partial L_t}$$

The magnitude of $C_t$ at any period depends directly on the physical productivity of labor; and under technical conditions where the firm's *earnings per worker* can be increased through an enlargement of the labor force,[9] the term $\partial U/\partial C_t \, \partial C_t/\partial L_t$ will be positive. But according to (3), the other terms deciding the value of $\partial U/\partial L_t$ are always negative. Thus, the positive productivity effect of increased labor can be offset. Moreover, if $L_t$ is increased sufficiently, the productivity effect may become negative; and, in addition, strongly adverse environmental and political effects will be generated. Ultimately, the latter must dominate because, beyond some point, enlargement of the labor input will cause the

[9] See the author and Svetozar Pejovich (1970, pp. 434–37). Change in the variable $C_t$ implies a change in the income or consumption achieved by the original membership of the collective ($L_1$). See equation (10) below.

original majority to lose assured political control of the firm and, hence, to lose control over all of the variables deciding the utility level.

Of course, the obvious strategy to guard against such an outcome is found in restriction of employment. The original majority can be conceived as establishing an *upper limit* on the total size of the working collective:

$$(5) \qquad L_t \leq \hat{L} \quad t=2, 3, \ldots, T$$

As the inequality suggests, the firm's labor input is open to variation from period to period, but in no instance will the number of workers exceed the limit indicated by $\hat{L}$. The parameter $\hat{L}$ reflects the group's judgment on how large a work force can be tolerated if effective political control is to be maintained. The relations (5) and (4) together define the attitudes or preferences of the original majority relative to policy choices for the firm.

## II. The Income Choices Facing the Collective

The given technical, economic, and institutional parameters of the firm impose limits on the rewards the organization can provide for its members. In effect, there exists a set of alternative time streams of real income that is attainable, and the decision makers must choose from among the options in this set. It is important to recognize, however, that the income streams have both pecuniary and nonpecuniary components; thus, something beyond simple monetary accounting is needed. The nature of the choice set can be clarified by considering some specific examples of the rewards that are available. In the simplest case, the decision makers may follow the elementary strategy of doing nothing and merely maintain the firm's initial factor endowment ($L_1$, $K_1$). Then *ceteris paribus*, the workers' pecuniary income will be the same period after period to the planning horizon. This approach avoids any environmental or political changes (nonpecuniary effects) by freezing the voting population at $L_1$, but it also rules out the possibility of the firm achieving a superior income stream. And the latter result is certainly conceivable. By varying $L_t$ or $K_t$, or both, it may be possible for the decision makers to generate pecuniary and nonpecuniary returns that represent a higher level of total utility than that offered by the status quo strategy ($L_1^0$, $K_1^0$).

If the firm's capital stock is to be increased beyond the initial level, a definite plan to finance the expansion has to be established. Logically, three alternatives are open; capital accumulation can be financed entirely by externally supplied credit, entirely by the firm's retained earnings, or by a combination of credit and self-finance. In the interest of simplicity, however, the present model will assume that the self-finance option represents the *only* means by which the firm can provide for capital expansion. In other words, no long-term investment funds are available from the banking system, the central government, or any other external agency. For the capital stock to be enlarged, the workers must elect to reduce the wage fund in some period or periods and "invest" in the firm.

Each investment program considered is necessarily associated with a complementary employment program and, thus, with certain *nonpecuniary* effects (via the $X_{kt}$ variables) that influence total satisfaction. Nevertheless, if the preferences of the original majority are well defined in (4) and (5), an assessment of the net benefits of any investment-employment strategy can always be made. By manipulating $K_t$ and $L_t$, the decision makers are able to establish an ideal balance between pecuniary and nonpecuniary rewards. The result represents the best stream of real income that can be obtained when reliance

is placed *solely on the resources of the firm.*

Unfortunately, however, the choice problem facing the collective is more complex than that of selecting the most desirable real income stream from the set of alternatives made possible by the firm's operations alone. Another basic investment option exists for the workers but this option has its origin *outside the firm.* Even under labor-management, an individual is permitted to save and acquire assets in the form of deposits at a state bank. Since savings deposits yield interest, individual investment in these fully owned funds constitutes a genuine alternative to collective investment in the firm. What emerges, then, is a system where the choice set includes two distinct types of income generating assets. That is, significantly different property rights attach to (owned) savings deposits and (nonowned) capital goods, but the workers have to judge the relative attractions of these two forms of wealth and allocate their savings between the two in optimal fashion.

The latter task is not without its difficulties. This is so because in general it is not possible to make *direct* comparisons between the rate of return on owned assets ($s$) and the rate of return on investment in the firm ($r'$). Differences in property rights account for the problem here. In the case of self-financed investment in capital goods, the principal sum (as such) is never returned to the workers. By contrast, savings banks return both interest and principal. Thus, to assess the true pattern of yields in existence, certain adjustments have to be made. In effect, the return on capital invested in the firm ($r'$) has to be reduced via an appropriate conversion formula to a level ($r$) that workers can compare meaningfully with the return on savings deposits ($s$).

The details of the conversion procedure will be explained below. At this point, it is sufficient to say that correction can be made for the different conditions of ownership and that, depending on the parameters characterizing the labor-managed system, the investment solution reached by the firm's workers will assume one of three possible forms. These are: case (i) Voluntary self-financed investment in the firm is zero and all of the savings recorded by the collective are channeled into deposits at the state banks; case (ii) No funds are allocated to savings deposits but, instead, any income not consumed is devoted to investment in capital goods for the firm; and case (iii) The collective's savings are allocated both to bank deposits and to investment in nonowned capital goods. The precise formal conditions that must be met for each of the respective cases to appear are developed from the general optimization model of the firm and will be presented in Section IV.

With this brief outline of the collective's choice problem in mind, the next step is to examine more closely the different possibilities workers have for securing income over time. The basic stream of revenues comes from the firm itself; and what is needed for the model is an analytical formulation defining the various operating positions permitted by the technical, economic, and institutional characteristics of the production unit. To this end, a so-called "consumption opportunity" locus can be established as follows.

By assumption, the firm's output is produced subject to the stock-flow production function (1). Then, if the firm is competitive and can sell any output at a fixed price $P_t$ set by the government, the profit function emerges as:

$$\Pi_t = P_t \cdot f(L_t, K_t) - Z(K_t) \tag{6}$$

The firm's "profit" in any period ($\Pi_t$) is the difference between total sales revenue and the corresponding "production expenses" indicated by the function $Z(K_t)$.

Production expenses include such outlays as depreciation charges, expenditures on raw materials, interest payments on government-owned capital, etc.; and for convenience the total cost here is taken to be a single valued function of the capital stock.

Under the labor-managed system, the firm's workers are empowered to decide on wage policy. Effectively, this means that the original majority allocates enterprise profit ($\Pi_t$) each period between the wage fund ($S_t$) and the investment fund ($I_t$).[10]

$$(7) \qquad \Pi_t = S_t + I_t, \qquad \Pi_t \geq I_t \geq 0$$

This accounting presupposes that workers are willing to consider the possibility of investing in the firm, and the idea is not unreasonable. While the worker-investors have no transferable rights in any capital accumulated through such *self-finance* activity, they can look forward to higher wages in future periods if the capital increments increase the average productivity of the labor force. In effect, the workers are able to make perpetual investments in the firm and secure "dividends" in the form of enhanced wages. As in the conventional case, investment in what can be termed "nonowned" assets implies an immediate sacrifice because current wages become progressively lower as the allocation $I_t$ increases and the wage fund $S_t$ diminishes.[11]

When the initial employment level is $L_1$ and the initial capital stock is $K_1$, it follows from (6) that the amount of profit is determinate—say, $\Pi_1$. Then, assuming that all of the wage payments go into consumption each period ($S_1 = C_1$), the level of self-financed investment $I_1$ must vary with the desired magnitude of $C_1$:

$$(8) \quad I_1 = P_1 \cdot f(L_1, K_1) - Z(K_1) - C_1$$

[10] Other internal funds are conceivable but are not considered in the model. See the author and Pejovich (1972, pp. 284–87).

[11] See the author (1971, p. 186), Atkinson, pp. 390–91, Vanek (1970, pp. 307–08).

Positive investment has consequences for the firm's position in the next period. If $p$ represents the fixed price per unit of capital equipment, an outlay of $I_1$ dinars translates into a certain number of physical capital units ($I_1/p$) that the firm can add to its existing capital stock ($K_1$) and utilize in the second period. Of course, under long-run conditions, the labor input ($L_t$) may also change along with the capital stock so that the size and composition of the collective changes.[12] The investment situation in period two is analogous to that of the first period. Both the output and total profit of the firm are larger, but self-financed investment depends on the collective's consumption choice ($C_2'$).

$$(9) \qquad I_2 = P_2 \cdot f(L_2, K_1 + I_1/p) - Z(K_1 + I_1/p) - C_2'$$

Here the variable $C_2'$ represents the total consumption of the *new, larger collective*. Its magnitude, however, emerges from the decision of the *original majority* on the ideal size of the wage fund ($S_2 = C_2'$). Of course, following similar reasoning, it is possible to establish the firm's investment equation for each successive period to the planning horizon T. At every stage, the labor force may be varied and a new political constituency may come into existence; the extent of the hiring each period will be determined as part of the solution to the majority's optimization problem. As long as the original majority retains control, both the firm's investment and employment policies will be decided by this dominant group to serve its own interests.

The immediate objective is to derive the

[12] It is assumed here that a competitive firm is able to recruit additional workers with little difficulty. Note, however, that the worker who contemplates joining a new firm must consider not only the current wage but the prospective time stream of pecuniary and nonpecuniary income he is likely to secure by joining the new organization.

consumption opportunity locus *that is perceived by the initial majority of the collective.* This particular construct is necessary because in formulating the optimization model, the variables in the constraint and the variables in the group preference function (4) must be consistent. As a practical matter, the consumption variables $C_2'$, $C_3'$, . . . , $C_T'$ have to be translated into new terms that reflect the options available to the membership of the original collective. First, a purely mechanical adjustment can be made. Assuming that the wage fund is always divided equally among all of the employees of the firm, we have:

$$(10) \qquad C_t = \frac{L_1}{L_t} \cdot C_t', \qquad t = 2, 3, \ldots, T$$

Each period, a proportional share of the firm's wage fund goes to the original members ($L_1$) and is spent by them on consumption as $C_2, C_3, \ldots, C_T$.

With the information supplied by (10), it is possible to rewrite the firm's investment relations. Equation (8) remains the same but all the others change so that the new system becomes the equations shown as (11). *Ceteris paribus*, the volume of self-financed investment planned in any period depends on the contemporaneous volume of consumption by the *original membership* of the collective ($C$); and this volume of consumption is in turn decided by the initial majority. Moreover, assuming that the latter group conforms to rule (5) and restricts employment so as to maintain political control, it follows that $I_T$ must be equal to zero. There is no financial incentive for workers who are about to retire to invest in the firm during period T.[13]

System (11) is so constituted that an investment expression for any period t can be substituted into the succeeding equation relating to period t+1. For example, the expression for $I_1$, involving $L_1$, $K_1$, and $C_1$, can be substituted into the second equation; and, then, the expression for $I_2$ can be introduced into the next equation, etc. As a result of successive operations of this type, the desired opportunity locus is obtainable.

$$(12) \qquad \Psi(C_1, C_2, \ldots, C_T, L_1, L_2, \ldots, L_T) = 0$$

According to our assumptions, $L_1$, $K_1$, and certain market and technical parameters are given; the remaining elements $C_t$ and $L_t$ are variables of direct interest to the decision makers. Operating positions desired by these workers will always lie on the opportunity locus rather than below it, and thus (12) is written as an equality.

## III. The Optimization Problem Restated

For the purposes of exposition, it will be convenient to develop the formal theory of the labor-managed firm in two stages. First, the long-run adjustment process of the firm will be explained on the assumption that decision makers have *only one in-*

[13] Workers might desire to invest in the firm, not for personal gain but for altruistic or patriotic reasons. On balance, however, it does not seem likely that investment motivated in this way will be quantitatively significant.

$$(11) \qquad \begin{aligned}
I_1 &= P_1 \cdot f(L_1, K_1) - Z(K_1) - C_1 \\
I_2 &= P_2 \cdot f(L_2, K_1 + I_1/p) - Z(K_1 + I_1/p) - \frac{L_2}{L_1} C_2 \\
&\vdots \\
I_T = 0 &= P_T \cdot f\left(L_T, K_1 + \sum_{t=1}^{T-1} I_t/p\right) - Z\left(K_1 + \sum_{t=1}^{T-1} I_t/p\right) - \frac{L_T}{L_1} C_T
\end{aligned}$$

*vestment option*. Specifically, the initial optimization model will presuppose that the controlling group chooses, each period, between self-financed investment in the firm and consumption. Then, after the characteristics of this basic construct have been established, the model will be extended to consider the behavior of the firm when savings banks exist and workers have choice among consumption, savings deposits, and self-financed capital investment.

Turning to the first task, the approach is as follows. The key building blocks (4), (5), and (12) suggest that the problem is one of constrained maximization. From the standpoint of the original majority of the collective, the objective is to maximize the multiperiod utility index (4) subject to a series of constraints.[14] Thus:

$$\text{(13)} \qquad \text{Max } U = \phi[C_t, \theta_{kt}(L_t)],$$

$$t = 1, 2, \ldots, T \quad k = 1, 2, \ldots, s$$

subject to $\Psi(C_t, L_t) = 0$,

$$C_1 \leq P_1 \cdot f(L_1, K_1) - Z(K_1) = G_1(L_1)$$

$$\frac{L_2}{L_1} C_2 \leq G_2(C_1, L_1, L_2)$$

$$\vdots \qquad \vdots \qquad \vdots$$

$$\frac{L_{T-1}}{L_1} C_{T-1} \leq G_{T-1}(C_1, C_2, \ldots, C_{T-2}, L_1, L_2, \ldots, L_{T-1})$$

$$L_t - L_1 \geq 0, \qquad t = 2, 3, \ldots, T$$

$$\hat{L} - L_t \geq 0, \qquad t = 1, 2, \ldots, T$$

$$C_t \geq 0, \qquad t = 1, 2, \ldots, T$$

Apart from the fundamental limitation on consumption possibilities imposed by locus (12), certain other restrictions hold because the collective is not permitted to borrow against its expected future income, or to liquidate existing capital stock, in order to increase the wage fund and consumption in any current period.[15] Thus, $C_1$ can be no larger than the firm's total profit in period one, and an analogous limit applies to consumption in each subsequent period. These constraints are obtainable from (11); *ceteris paribus*, the maximum consumption in any period t appears when $I_t = 0$.

Since there are political and other reasons why the labor-managed firm may find it difficult to discharge employees,[16] the model confines attention to the expansion of the firm and assumes that total employment will never fall below the given initial level. The condition $L_t \geq L_1$ holds; but taking account of the upper limit on employment (5), it is also true that $L_t \leq \hat{L}$. Finally, in view of the definitional scheme used in the model, rational interpretation of (13) requires nonnegativity conditions to hold for the variables $C_t$.

Consideration of the mathematical properties of system (13) suggests that the maximization problem can be solved by using the quasi-concave programming methods developed by Kenneth Arrow and Alain Enthoven. Specifically, if the objective and constraint functions in (13) are differentiable and quasi concave, and if the system meets certain other mild requirements, the standard Kuhn-Tucker conditions are both necessary and sufficient for

[14] The model assumes that the majority group possesses certain information about the system in period one, and that on the basis of this information, the group can formulate plans for the optimal adjustment of productive inputs for all remaining periods to the planning horizon. It does not necessarily follow, however, that the plans made in period one will all be carried out. As new information and experience come to the firm over time, the optimization procedure can be repeated. In principle, successive output-investment-employment plans covering periods 2, 3, . . . , T; 3, 4, . . . , T; etc., could be established period after period as the original horizon is approached more closely and more information is available—particularly on political events within the firm.

[15] The restrictions conform to the laws of Yugoslavia.

[16] See the author and Pejovich (1973, pp. 283–86).

a constrained maximum of $\phi$. These technical conditions can be met. The group utility function (2) is ordinal and can be taken as globally strictly quasi concave because it is plausible to assume that the marginal rate of substitution between any pair of variables in the function $\phi(C_t, X_{kt})$ increases monotonically as more of one item is substituted for the other. Ultimately, of course, function (4) appears in the optimization model, but the transformation of (2) into (4) does not change anything essential. Equation (4) is also strictly quasi concave and no difficulty need arise here.[17] The shape of the opportunity locus $\Psi$ as well as the characteristics of the consumption restrictions are determined by the nature of the firm's production function. And when the latter is homogeneous of degree one, all is well. For example, $\Psi$ is clearly concave (and hence quasi concave) if either the labor input or the capital input is held constant while the other is varied. Similarly, if the firm varies both inputs in the same proportion, the opportunity locus will be linear (and quasi concave). The mathematical properties of the constraints become troublesome only when the production function shows increasing returns to scale. But even then reasonable solutions are always possible because of the existence of the upper limit on employment ($\hat{L}$). There are no circumstances in which the firm can pursue sustained expansion subject to increasing returns.

System (13) is formulated so as to emphasize the economic logic of the model and because of this, certain constraints are not set up in standard form for mathematical programming. In what follows, however, the problem will be transformed appropriately—while preserving the quasi concavity of the relations in (13). Then, familiar procedures can be used to obtain the ideal long-run plan for the firm. The first step is to set up the Lagrangian function:

$$
\begin{aligned}
(14)\quad & F(C_t, L_t, \lambda_r) \\
&= \phi[C_t, \theta_{kt}(L_t)] + \lambda_1\Psi(C_t, L_t) \\
&\quad + \lambda_2[-\Psi(C_t, L_t)] \\
&\quad + \lambda_{31}[G_1(L_1) - C_1] + \dots \\
&\quad + \lambda_{3T-1}\left[G_{T-1}(C_1, \dots, C_{T-2}, \right. \\
&\quad \left. L_1, \dots, L_{T-1}) - \frac{L_{T-1}}{L_1} C_{T-1}\right] \\
&\quad + \sum_{t=2}^{T} \lambda_{4t}(L_t - L_1) \\
&\quad + \sum_{t=1}^{T} \lambda_{5t}(\hat{L} - L_t)
\end{aligned}
$$

The relevant Kuhn-Tucker conditions are:

$$
\begin{aligned}
(15)\quad & \frac{\partial F}{\partial C_t} \leq 0, \quad C_t \geq 0, \quad C_t \frac{\partial F}{\partial C_t} = 0 \\
& t = 1, 2, \dots, T \\
& \frac{\partial F}{\partial L_t} \leq 0, \quad L_t \geq 0, \quad L_t \frac{\partial F}{\partial L_t} = 0 \\
& t = 1, 2, \dots, T \\
& \frac{\partial F}{\partial \lambda_r} \geq 0, \quad \lambda_r \geq 0, \quad \lambda_r \frac{\partial F}{\partial \lambda_r} = 0 \\
& r = 1, 2, \dots, 4t, \dots, 5T
\end{aligned}
$$

With the mathematical properties assumed for the model, conditions (15) are both necessary and sufficient for a constrained maximum of $\phi$.[18] A solution is ob-

[17] The indifference contours of function (4) involving $C_t$ and $L_t$ will show positive slopes, but each such contour represents the lower boundary of a convex set and, thus, quasi concavity is present. See Arrow and Enthoven, p. 780.

[18] The constraint set is convex and thus the Kuhn-Tucker constraint qualification holds. Further, the criterion function (4) is defined so that satiation is ruled out. See Arrow and Enthoven, pp. 790–91, and Blaine Roberts and David Schulze, pp. 377–89.

tainable therefore and what it represents is a set of ideal, or utility maximizing, values for the consumption and labor variables—viz., $C_1^*, C_2^*, \ldots, C_T^*, L_1^0, L_2^*, \ldots, L_T^*$. Of course, knowing these, it becomes possible to go back through the system of equations and determine for each period of time to the horizon the optimal levels for: (i) the environmental indexes ($X_{k_t}^*$); (ii) self-financed investment ($I_t^*$); and (iii) output ($q_t^*$).

It should be reemphasized that the respective "optimal" values are optimal from the standpoint of the *original majority* whose preferences are reflected in (4) and (5). Such preferences can take on various configurations and thus the firm's behavior is subject to wide variation. The decision makers may approve self-financed investment and values of $I_t^*$ greater than zero but, on the other hand, a type of *corner solution* can occur if the original majority has great impatience for present consumption and establishes time-indifference manifolds that preclude any sacrifice of current consumption for investment purposes. Similarly, the placement of $\hat{L}$ can allow wide latitude for change in the employment level or constrain the firm to remain at $L_1$. Naturally, there are other parameters of importance in the system beyond those relating to the utility function and the employment limit. The model summarized in (13) is written in highly general notation and this treatment, while saving space, does tend to obscure some significant details. If a more explicit mathematical formulation were given to (13), greater attention could be focused on: (i) the technological coefficients of the production function; (ii) the commodity and factor prices ($P_t, p$) embedded in locus (12) and in the other consumption constraints; (iii) the characteristics of the expense function ($Z$); (iv) the firm's initial factor endowment ($L_1^0, K_1^0$); (v) the internal political conditions of the collective and the size of the original majority group; (vi) the shapes of the conversion relations ($\theta_{kt}$); and (vii) the planning horizon adopted by the decision makers (T).

The particular equilibrium solution reached by the firm depends on the values of all these elements, and any variation in such values must lead to a shift in the firm's position. As a practical matter, the effects of parameter change could be assessed systematically by using comparative statical analysis, but this extension lies beyond the objectives of the present paper. While the significance of changes in the planning horizon for allocative efficiency will be considered in Section IV below, T is the only parameter that is singled out for special study here.

In general, however, the response of the decision makers to policy choices can be analyzed as follows. From (15), it is apparent that at equilibrium the marginal rate of substitution between any two variables in the utility function, as $C_i > 0$, $C_j > 0$, is equal to the ratio of the marginal imputed "costs" associated with these variables. Thus:

$$(16) \quad -\frac{\partial C_j}{\partial C_i} = \frac{\left.\dfrac{\partial U}{\partial C_i}\right|_{C_i^*}}{\left.\dfrac{\partial U}{\partial C_j}\right|_{C_j^*}} = \frac{\sum_{h=1}^{m} \lambda_h^* \left.\dfrac{\partial V_h}{\partial C_i}\right|_{C_i^*}}{\sum_{h=1}^{m} \lambda_h^* \left.\dfrac{\partial V_h}{\partial C_j}\right|_{C_j^*}}$$

where $V_h$, $h=1, 2, \ldots, m$ represent the constraint functions of the system that are *binding* on the variables $C_i^*$, $C_j^*$ at equilibrium, and $\lambda_h^*$, $h=1, 2, \ldots, m$ are the corresponding Lagrangian multipliers. The latter, of course, are all greater than zero. Costs arise in the situation considered because greater consumption in any period $t=i$ implies via constraint (12) some reduction in the consumption levels, and possibly in the environmental quality levels ($X_{kt}$), at other periods coming before or after $t=i$. Whether intertemporal ($\partial C_j/\partial C_i$) or "intercommodity" ($\partial C_t/\partial L_t$)

tradeoffs are considered, the original majority must always balance prospective utilities against opportunity costs. In this way, substitutions proceed until the optimal plan has been formulated and no further advantageous reorganizations can be made.

## IV. Savings Deposits and the Behavior of the Firm

The model discussed in Section III applies to a labor-managed firm operating in an environment where self-financed investment in nonowned assets represents the *only alternative* to consumption. But, as noted earlier, decision makers also have the possibility of owning interest bearing savings deposits; and the existence of this option changes the situation considerably. With investment choice enlarged, the behavior of the firm predicted by system (13) does not necessarily come about. That is, the solution values $C_t^*$, $L_t^*$, $I_t^*$, etc. do not hold unless the magnitudes of certain critical parameters fall into a special pattern. To understand the new (extended) choice problem, it is essential to relate the basic optimization model (13) to the income opportunities offered by the savings banks. When both owned and nonowned assets exist, what takes on central importance for the behavior of the firm is the volume of investment planned in *each asset category*. How this key investment decision is made, and how the investment "portfolio" chosen affects the firm's operations, will be explained in detail below.

One of the fundamental building blocks of model (13) is the consumption opportunity locus (12). The latter defines the set of consumption or income alternatives the firm's resources can provide for the workers. In general (12) indicates that many different time streams of consumption are attainable, but the relation also implies that at any given time period t the next period's choices reduce to:

$$(17) \quad C_{t+1} = H(L_{t+1}, C_t, L_t, \ldots, C_1, L_1)$$

Broadly speaking, the consumption level at t+1 depends on the consumption-investment-employment decisions that have been implemented in the past. At the end of period t, the only variables subject to policy choice are $C_t$ and $L_{t+1}$. Consequently, if $L_{t+1}$ is specified, the variable $C_{t+1}$ becomes a function of $C_t$. In other words, the level of consumption (income) in t+1 has a systematic linkage with the savings and investment behavior of the collective in period t.

Given the past actions of the firm, the maximum consumption level attainable in period t is easily established. This value, say $C_t^0$, results if decision makers refuse to undertake any self-financed investment ($I_t$) in period t. But if $I_t$ is zero, the firm's capital stock does not change. Then, given a value for the labor input $L_{t+1}$, the feasible consumption of the collective ($C_{t+1}^0$) in period t+1 becomes determinate via (6). Of course, as $I_t$ is increased from zero, actual consumption ($C_t$) in period t falls but consumption ($C_{t+1}$) in period t+1 increases. The tradeoff here can be explained in familiar terms. Since it is assumed that $L_{t+1}$ is specified (and since, in any case, an upper limit $\hat{L}$ exists on employment), diminishing returns to capital investment must ultimately appear; in short, the magnitude $C_{t+1}$ must increase at a decreasing rate if the sacrifice of $C_t$ is pushed far enough.

The preceding discussion provides the basis for defining the *average rate of return* ($r'$) on capital invested in the firm. Thus for any two periods t and t+1, we have:

$$(18) \quad r' = \frac{C_{t+1} - C_{t+1}^0}{C_t^0 - C_t} = \frac{C_{t+1} - C_{t+1}^0}{I_t}$$

The consumption level $C_{t+1}^0$ can be achieved when $I_t$ is zero, and it is the difference between this value and the higher

consumption level made possible by positive investment that represents the gain from investment observable in period t+1. The gain in real income is, however, not limited to period t+1. Since the larger capital stock will be sustained indefinitely over time, the increment $(C_{t+1}-C^0_{t+1})$ will appear each period in perpetuity. Equation (18) is then a valid expression for determining the average rate of return.

Under labor-management, the value of the firm's capital stock must be preserved in perpetuity; moreover, the value of any additions to the original stock must also be maintained, regardless of how these additions have been financed. This institutional arrangement has the effect of making self-financed capital accumulation much less appealing in practice than the magnitude of the average rate of return $(r')$ might suggest. Worker-investors do not have permanent claim on the capital stock of the firm and cannot sell their income rights to others when they leave the organization. Thus, to secure appropriate reward, workers must get back both principal and interest payments from the larger stream of income or *wage earnings* investment brings about, and they must do this during the period of time they remain with the firm.

The situation just described means that the effective return on nonowned assets is less than $r'$; correction has to be made for the special property rights structure extant. From the standpoint of actual investment behavior, the relevant rate is determined as follows:

$$I_t = \sum_{\tau=t+1}^{T} \frac{(r' \cdot I_t)_\tau}{(1+r)^\tau} \tag{19}$$

Here, $r$ is the *corrected average return;* it is the average rate of return when adjustment has been made for the length of the collective's planning horizon (T) and for the fact that the principal sum invested $(I_t)$ is never returned as such. Obviously, (19) is nothing more than a present value formula. The expression in the numerator represents the gross increase in income $(C_{t+1}-C^0_{t+1})$ that can be secured *each period* from period t+1 to period T as a result of the self-financed investment $I_t$. Since increments to the firm's capital stock are maintained perpetually, any gain in consumption (income) realized through investment can be sustained to the planning horizon without any further sacrifice by the workers in periods after t.[19] The important thing, though, is that with the aid of (19), any uncorrected rate of return $r'$ can be translated into a corresponding $r$ value that is directly comparable with the return on fully owned assets $(s)$.

For convenience, it will be desirable to rewrite (19) in simpler notation:

$$r = r(I_t, L_{t+1}) \tag{20}$$

The equation presupposes an extensive set of background conditions relating to employment and the firm's capital stock but *ceteris paribus* the average return depends on self-financed investment in period t. Similar expressions for the corrected rate of return could be developed for each period to the planning horizon T. By definition, $rI_t$ gives the total increase in income or consumption $(C_{t+1}-C^0_{t+1})$ that the collective can enjoy per period from period t+1 to period T as a result of an investment $I_t$. The product $rI_t$ represents a *net* increment to income in the sense that full adjustment has been made for the property rights structure. Then, differentiating this product partially with respect to $I_t$ establishes the *corrected marginal return* to capital:

$$\frac{\partial[r(I_t, L_{t+1}) \cdot I_t]}{\partial I_t} = r + I_t \frac{\partial r}{\partial I_t} \tag{21}$$

[19] It is assumed that at each period t+1 through T, the entire increase in the firm's profit $(\Delta\Pi_\tau)$ attributable to the added capital goods $(I_t)$ is paid out in the form of higher wages. Other plausible assumptions about the reward stream are conceivable and can be handled in variant formulations of (19).

The condition derived is important because it shows the change in the magnitude of the (adjusted) consumption increment that occurs in response to an additional small outlay on investment in nonowned assets. Since it is known from the structure of the model that both $r'$ and $r$ must ultimately fall as $I_t$ increases, the product $rI_t$ must ultimately *increase at a decreasing rate* and thus the marginal curve (21) has to fall. That is, in interpreting (21) it should be understood that $\partial r/\partial I_t < 0$.

The expression for the corrected marginal return to investment was obtained directly from model (13) and reflects the productive options open to the labor-managed firm. What has to be done next is to link this condition with the reward that can be secured from fully owned savings deposits. In a system where both owned and nonowned assets are available, utility maximization has to proceed subject to the various constraints specified in (13) and in addition must be consistent with the following requirement:

$$(22)\quad r + I_t \frac{\partial r}{\partial I_t} \geq s, \quad \mathrm{t} = 1, 2, \ldots, \mathrm{T} - 1$$

At any period t, a greater or lesser volume of self-financed investment may be undertaken but, at the margin, the effective productivity of such investment must be greater than or equal to the interest yield on savings deposits ($s$). The rationale for (22) rests on considerations of efficiency; *ceteris paribus* each dollar of savings generated by the collective should be allocated to the most remunerative alternative open. From the standpoint of optimization, additional investment in the firm is justified as long as more capital adds to the total satisfaction (utility) of the decision makers and brings in a return at least as great as the return that would result if the same sum were applied to savings deposits. Of course, once the marginal return to investment sinks below $s$, the collective's funds can be put to better use in banks and investment in nonowned assets should be ended.

When the basic model of the labor-managed firm is modified by the introduction of (22) as an additional constraint, the behavior of the firm is seen in new perspective. Together, systems (13) and (22) can yield three distinct types of solutions:

*Case (i)*: There will be no incentive for workers to invest in the firm if productivity conditions are such that the corrected marginal return (say $m$) is consistently low relative to the interest rate ($s$). That is, self-finance is completely ruled out if $m$ is *less than* $s$ for all positive values of $I_t$ in period one, and in each subsequent period. When $m$ is always less than $s$, workers seeking to maximize utility must: (a) make the size of the wage fund as large as possible consistent with environmental and political concerns, and (b) allocate whatever savings are desired to savings accounts at the state banks. The implications of this type of program for the firm's actions can be summarized as follows:

$$(23)\quad \begin{aligned} I_t &= 0 & \mathrm{t} &= 1, 2, \ldots, \mathrm{T} \\ \overset{0}{L_1}, L_t &= L' & \mathrm{t} &= 2, 3, \ldots, \mathrm{T} \end{aligned}$$

In other words, investment in the firm is nil, but depending on the initial capital-labor ratio and majority preferences (4), some adjustment may be made in the labor input. For example, the labor force may be enlarged in period two (to $L'$) in order to increase the firm's profits and the wage fund. Once the equilibrium adjustment has been achieved, though, no further variation in labor is justified because no change occurs in the capital stock over time. Of course, if the initial conditions do not warrant any departure from the original employment level, $L_1^0$ will be the labor input for all periods to T, i.e., $L' = L_1^0$.

*Case (ii)*: If workers have relatively

limited desire to forego current consumption in order to invest and if the productivity of capital in the firm is high, investment may be confined exclusively to nonowned assets. In such case, no funds will be allocated to savings deposits (owned assets) because in any period when positive investment is undertaken, the corrected marginal return ($m$) remains greater than the rate of interest ($s$). Given the parameters, the constraint imposed by voluntary saving always becomes binding before the return $m$ falls to the level of the interest rate $s$. As far as the behavior of the firm is concerned, the outcome here is essentially like that described by the basic model of Section III, i.e., system (13) without the addition of (22). Practically, the existence of the savings bank option does not influence the solution; the solution values reached ($C_t^*$, $L_t^*$, $I_t^*$, $t=1, 2, \ldots, T$) are independent of the rate of interest $s$ as long as the latter does not rise beyond some critical limit.

Since long-run conditions are assumed, the firm is able to vary both the labor and capital inputs. It follows that the capital productivity schedule may be shifted to the right significantly; thus the possibility is increased for an equilibrium of the type where $m>s$. Specifically, if increasing returns to scale hold, the marginal return to investment in the firm will rise over at least a limited range. Then, unless $s$ is greater than $m$ at the outset, no incentive will exist to place funds in savings deposits within that range. The upward course of $m$ will not continue indefinitely, however, because of the reluctance on the part of the initial majority to increase the labor force. Even under the most favorable circumstances, capital accumulation by the firm has definite limits.

*Case (iii)*: When the model is characterized by a still different set of parameters, workers can find it optimal to invest in both owned and nonowned assets simultaneously. This result will tend to occur in situations where the decision makers have substantial willingness to save and/or where the productivity of capital in the firm is low and falls rapidly. In other words, as $I_t$ is increased in any period, the marginal return $m$ can fall to the level of the interest rate $s$ before the savings constraint becomes binding. Thus, (22) holds in the form of an equality ($m=s$) in some or all periods. Beyond the point at which $m=s$, workers still wishing to save can divert funds to savings deposits and earn interest at rate $s$. Both types of assets, then, are taken simultaneously. It is possible for the firm to increase its capital stock but under the conditions of Case (iii), the decision makers will restrict the investment in nonowned assets relative to what would occur in a system where no savings banks existed.

In each case considered above, the fundamental problem for the collective is to maximize utility function (4) subject to certain constraints, including condition (22). As has been shown, various types of solutions emerge depending in an immediate sense on whether: (i) $s>m$; (ii) $m>s$; or (iii) $m=s$. Regardless of what form the solution takes, however, a definite policy line is defined for the firm, and the nature of the firm's long-run behavior can be predicted.

## V. Allocative Efficiency under Labor Management

The question of what constitutes an efficient pattern of resource allocation within a labor-managed economy is complex and can be argued at different levels.[20] For purposes of the present discussion, however, it will be sufficient to accept the view that allocative efficiency holds when certain familiar marginal rules are met.

[20] See Maurice and Ferguson, pp. 23–27, and Vanek (1969, pp. 1010–11).

In other words, an equilibrium reflecting Pareto optimality is taken as the desideratum, and what has to be decided here is whether the behavior of the labor-managed firm is likely to be consistent with this idealized state. Vanek (1969, p. 1007), for one, argues that Pareto efficiency will prevail provided perfect competition rules and, in particular, that there is free entry for firms employing identical technologies. The conclusions of the model developed above do not support such a presumption, however, and the reasons why allocative difficulties can be expected are easily demonstrated.

The literature has shown that in the case of a firm operating over time subject to a stock-flow production function, intertemporal efficiency requires only myopic vision on the part of decision makers. Specifically, an optimal allocation program for the competitive firm will result if, at each cross-section of time, resources are employed in such way as to equate the marginal rate of substitution between any pair of inputs ($\partial K_t/\partial L_t$) with the ratio of their effective prices (rental rates) in that period.[21] Then, considering the simplest possible situation where the initially given product and factor prices are expected to hold unchanged to the planning horizon, it is clear that the firm's allocation pattern reduces to one that is frozen over time; each period, the unchanged price of a factor equals the value of its marginal product, and input flows must be the same in all periods through T. Under the latter conditions, it might be thought that the labor-managed firm could reach the ideal, or Pareto optimal, level of *capital stock* without difficulty if only the equilibrium rate of interest in the economy were known. That is, knowing the interest rate, the firm could in theory follow a standard decision rule and continue to add to its initial capital stock up to the point where the marginal return to capital invested in the firm was equal to the equilibrium interest charge. But, actually, the labor-managed firm will not act so as to attain this ideal position. In general, the institutional structure militates against the possibility of the firm achieving an optimal capital stock.

[21] See Agnar Sandmo, pp. 1336–42.

One obvious trouble arises from the fact that the equilibrium rate of interest is not known. In a labor-managed socialist system, there is no free capital market and hence no practical way of establishing an unambiguous measure of the general opportunity cost of capital. This situation poses a serious problem for efficient allocation. Nevertheless, in order to place the labor-managed system in the best possible light, let us assume away the obstacle and accept the fiction that the equilibrium rate of interest ($s$) is known and *is equal to the rate paid on savings at the state banks.* As explained earlier, the firm's decision makers have a choice between investment in savings deposits and investment in the firm, i.e., between owned and nonowned assets. What has to be emphasized, however, is that the property rights arrangements in existence strongly affect the *relative attractiveness* of these two types of assets. And relative attractiveness is important, of course, because the decision taken on the type and amount of assets to be acquired exerts a direct effect on the input-output behavior of the firm over time.

Nonowned assets have lesser appeal than fully owned savings deposits for the simple reason that the property rights workers possess in nonowned physical capital are limited to *usus fructus.* In practical terms, this condition means that the firm has lesser incentive for capital accumulation than is desirable from a social point of view. From society's standpoint, the marginal return on an increment of

capital added to the firm is given by the relation:

$$\frac{\partial(r'I_t)}{\partial I_t} = r' + I_t \frac{\partial r'}{\partial I_t} = m' \tag{24}$$

where $r'$ is the average rate of return on capital (18) *uncorrected for workers' property rights*. Efficient allocation requires that the uncorrected marginal return ($m'$) be equal to the rate of interest ($s$) at equilibrium. But, as has been shown in Section IV, decision makers at the level of the firm are motivated to invest in nonowned assets only when the *corrected* marginal return ($m$) is greater than or equal to the interest rate ($s$). Obviously, the divergence between the needs of society and the needs of the firm must lead to difficulties.

If Case (i) holds and the corrected marginal return $m$ is always less than $s$, the firm's workers will commit all of their voluntary savings to owned assets. Self-financed investment will be zero and the firm will operate in accordance with the input plan described in (23). This choice, however, is consistent with a misallocation of resources because $m'$ can be greater than $s$ even though $m$ is less than $s$. In other words, it is possible for socially desirable investment in the firm to be neglected despite the fact that the true return on capital is greater than its opportunity cost ($m'>s$). The fundamental reason for the problem is revealed by equation (19). The average rate of return $r'$ must be greater than the corrected rate $r$ for every level of $I_t$ as long as the planning horizon T is finite. What represents a *perpetual* income stream from the standpoint of society ($r'I_t$ per period) is seen as a *finite* stream (to T) by the collective and thus $r'>r$. Of course, the distinction between the two marginal returns follows *mutatis mutandis*, and $m'$ is always greater than $m$. It is also clear that the extent of the difference between $m'$ and $m$ (for any $I_t$) becomes larger as the collective's planning horizon T is shortened.

Positive self-financed investment to increase the firm's capital stock is feasible provided $m \geq s$. The precise outcome here will be given by the solution values of system (13) and (22). While such investment in the firm may be desirable, it remains true that the condition $m \geq s$ *precludes allocative efficiency*. Pareto efficiency requires that investment be carried to the point where $m'=s$; but there is no chance for such a result to occur through worker investment in the firm. At best, Case (iii) holds and the firm's equilibrium will be reached where $m=s$. However, since $m'>m$, it follows that $m'>s$ and the process of self-financed capital accumulation must always be *relatively restricted*. If the firm does not commence its operations with the optimal capital stock, the optimal stock will not be reached.

Is there any escape from the difficulty just noted? It can be argued, of course, that the rate of interest offered on savings deposits does not have to be set at $s$. Individual savers could be confronted with a much lower rate (say, $s_0$) than the equilibrium rate of interest—even though this policy ($s_0<s$) might tend to reduce the volume of savings deposits. In any event, when a low value is established for $s_0$, and when the collective has a sufficiently long planning horizon so that the difference between $m'$ and $m$ is relatively small at each level of $I_t$, the possibility exists for resolving the conflict between the objectives of society and the firm. The separate conditions $m=s_0$ and $m'=s$ *may be met simultaneously*. The collective can find it advantageous to invest in nonowned assets up to the point where $m=s_0$; but given the right parameters optimal capital accumulation will also take place because $m'=s$ when $m=s_0$.

In a system where $m'>m$ and $s>s_0$,

manipulation of the $s_0$ value can be useful. There is, however, no assurance that the planning horizon chosen by the firm's decision makers will always be long enough to permit a sufficient reduction of $s_0$ and the possibility of $m'=s$ while $m=s_0$. Moreover, self-financed investment can easily be zero despite a low value for $s_0$ and a favorable value for T because other parameters are involved in the determination of investment policy. Ultimately, the firm's decision makers are concerned with the effect of investment on the utility index (4). This implies that nonpecuniary as well as pecuniary considerations affect the firm's choice of inputs. Thus, in so far as investment is tied to *expansion of the labor force*, the decision makers may anticipate political and environmental difficulties and vote to reject even those capital projects promising substantial pecuniary returns.

A striking feature of the labor-managed system is the restricted range of investment alternatives it allows the workers. Investment in education and training aside, an individual can choose to accumulate savings deposits, or to invest in his firm, or to do both simultaneously. This arrangement is unsatisfactory, however, because it means that the allocation of capital has to take place subject to inadequate information about other alternatives in the economy. Just as there can be too little investment by the firm, there can be too much if the bank rate $s_0$ is set significantly below the equilibrium rate of interest $s$. That is, at the level of investment $I_t$ where $m=s_0$, $m'$ can be less than $s$; and the result is that the volume of self-financed investment in the firm will then be too large. Inefficient allocation occurs here because the firm's decision makers are not aware of the true value of $s$ and, in any case, they are guided by the relative magnitudes of $s_0$ and $m$.

In general, as long as the corrected marginal return on capital is greater than or equal to the established interest rate ($m \geq s_0$), the investment solution will be made on the basis of the collective's subjective estimates of costs and benefits. The first-order conditions emerging from the solution of model (13) and (22) will decide the outcome independently of circumstances in the rest of the system. For example, assuming the collective's propensity to save is small, Case (ii) is likely to appear and the latter indicates that not even the equilibrium $m=s_0$ will be reached, to say nothing of $m'=s$. As far as the firm is concerned, then, the realization of an optimal capital stock is merely a possibility, a result that can come about only under very special conditions. At any moment of time, the labor-managed firm is controlled by particular individuals having the power to shape the firm's investment, employment, and output policies *to suit their own specialized objectives*. If the decision makers are rational and truly free to seek their own interests, it seems highly improbable that they will behave in the manner suggested by the simple wage maximization hypothesis.[22] In what is likely to be the typical situation, the firm's planning horizon will be relatively short, the wage rate will not be maximized each period, and factor allocation will not conform to the requirements for Pareto optimality.[23]

As explained, the original majority determining the firm's policy will normally find it desirable to limit the input of capital to levels below those required by orthodox

[22] See Ward and Vanek (1970).

[23] Note that the firm's *initial conditions* exert a significant influence on the nature and extent of the productive adjustments the collective will ultimately make. *Ceteris paribus*, the initial capital-labor ratio ($K_1/L_1$) determines the marginal productivity of capital and affects the incentives for subsequent self-financed investment. Similarly, the initially given political structure within the firm influences $\hat{L}$ and decides how far the original majority will be willing to proceed with the hiring of new employees.

marginal productivity considerations. But deliberate restriction of the firm's labor input is also to be expected. Because of the pressure of internal politics and concern for the firm's environment, there will be reluctance on the part of the original majority to increase the labor force. A simple illustration can be used to explain the factors affecting employment policy. Assume that the firm's production function is homogeneous of degree one and that the initial capital-labor ratio $(K_1/L_1)$ is *larger* than the equilibrium ratio required to maximize the wage per worker in the first period. Under these conditions, the employment of additional labor could raise the prevailing wage rate step by step until the maximum wage $(w_1^*)$ was reached. But from the standpoint of the original majority, the desirability of greater employment cannot be judged on the basis of productivity alone. As the first-order conditions (16) indicate, increased labor reduces utility via the effect on the $X_{st}$ variables, and influences subjective costs in so far as the employment constraint $\hat{L}$ becomes binding. Thus, employment may not be carried as far as the usual marginal logic $(P_1\partial q_1/\partial L_1 = w_1^*)$ would demand. Such restrictive behavior is quite rational from the standpoint of the decision makers, but its consequences for efficient resource allocation are predictably bad.[24]

It may seem anomalous that rational individuals would deliberately choose to operate with factor combinations that promise lesser output per worker rather than with alternatives having greater productivity. But as emphasized throughout the analysis, the choices made by the initial majority of the collective are perfectly understandable when the role of *appropriability* is recognized. The rewards that are meaningful to these workers are the pecuniary and nonpecuniary returns that they can actually capture during their period of tenure with the firm. Having neither permanent nor transferable claims on the assets of the labor-managed firm, decision makers operate with relatively short planning horizons and view economic choices in a somewhat distorted perspective. Policies that increase the wealth of the firm over some stretch of time, but do not improve the appropriable real incomes of the decision makers during this same period, are not likely to be considered desirable, and will tend to be rejected. Given these fundamental characteristics, the ultimate conclusion on the labor-managed firm is clear. Whatever its contribution to industrial democracy, it is not an inherently efficient economic organization.

[24] It can be noted here that the problems of allocative inefficiency remain to plague the firm whether or not the firm is able to draw upon bank credit or other external capital funds. See the author and Pejovich (1973, pp. 280–86) and the author (1974).

# Inflationary Expectations: Their Formation and Interest Rate Effects

*By* KAJAL LAHIRI*

In estimating the effects of inflationary expectations on nominal interest rates, distributed lags on past prices have generally been used as observable proxies for the supposedly unobservable price change expectations. Thus, Irving Fisher's famous explanation of the Gibson paradox is expressed in terms of two hypothesized relationships:

$$(1) \qquad rn_t = rr_t + \dot{p}_t^e$$

$$(2) \qquad \dot{p}_t^e = \sum_i w_i \dot{p}_{t-i}$$

The first equation states that the nominal interest rate ($rn_t$) for a particular asset with returns fixed in money terms is equal to the real rate of interest ($rr_t$) plus the anticipated rate of inflation ($\dot{p}_t^e$). He further assumed that $rr_t = \rho + u_t$ where $\rho$ is the long-run real equilibrium rate of interest and where $u_t$ is a random error term. Since equation (2) was used as a proxy for $\dot{p}_t^e$ in equation (1) the reduced form becomes

$$(3) \qquad rn_t = \rho + \sum_i w_i \dot{p}_{t-i} + u_t$$

and the whole problem finally boils down to that of finding out a particular lag structure which best explains the interest rate variations. Robert Gordon followed exactly the same approach to develop an independent measure of price expectations which was used for estimating wage-price equations.

It should be pointed out that the distributed lag coefficients of equation (2) can only be recovered from the reduced form estimates if the coefficient of price expectations in the interest rate equation is assumed to be unity; or some other assumption is made on $w_i$. As William Gibson has pointed out, there are important theoretical and empirical studies which suggest that the nominal rate of interest may not fully adjust to changes in price expectations. Thus, equation (1) should be modified as

$$(4) \qquad rn_t = \alpha + \beta \dot{p}_t^e + u_t$$

and ideally $\beta$ should be subject to usual statistical tests. In the context of equation (3) another assumption which identifies the parameter $\beta$ and which seems to be implicit in a number of studies is that $w_i$ sums to one. This restriction means that eventually people will catch on and fully anticipate inflation. It is certainly reasonable to expect that a sustained constant inflation sooner or later would be fully anticipated; but this consideration is of very little use in producing a reasonable restriction to impose on $w_i$ for the purpose of empirical estimation because during the periods used in estimation, inflation was never so sustained (see Thomas Sargent). Another problem associated with the distributed lag proxy is that it is modelled in a deterministic form which may be quite restrictive in diverse periods. More prop-

I am especially indebted to my adviser, G. S. Maddala, and to K. M. Gaver, D. J. O'Hara, Sherwin Rosen, and an anonymous referee for helpful comments. Responsibility for any errors is solely mine. Financial support from the National Science Foundation under grant GS-33356 to the University of Rochester is gratefully acknowledged. A special note of thanks is due to William Gibson for kindly supplying the data on observed price expectations.

erly, expectations should be modelled with an error:

$$\dot{p}_t^e = \sum_i w_i \dot{p}_{t-1} + \eta_t \tag{5}$$

Unfortunately modelling expectations stochastically results in a reduced form in which the explanatory variables are correlated with the composite error term. Hence ordinary least squares would give inconsistent estimates.

To overcome these difficulties Gibson and D. H. Pyle used the Livingston survey data (from Philadelphia Bulletin; for more information, see Gibson) on price expectations to test the Fisher effect. In some instances they found the value of $\beta$ to be far below unity. Stephen Turnovsky and Michael Wachter had noted in the context of their study of the Phillips curve that the coefficient might have been seriously underestimated due to the presence of some errors in the measurement of the variable. Gibson and Pyle, too, pointed out the same.

Turnovsky used the same data to study the lag structure of past prices that best explains the data on price expectations. The purpose of the present paper is to estimate the following structural model:

$$\dot{p}_t^* = \dot{p}_t^e + u_{1t} \tag{6}$$

$$rn_t = \alpha + \beta \dot{p}_t^e + u_{2t} \tag{7}$$

$$\dot{p}_t^e = \sum_{i=1}^{m} w_i \dot{p}_{t-i} + u_{3t} \tag{8}$$

where $\dot{p}_t^*$ = observed price expectations
$\dot{p}_t^e$ = unobservable price expectation variable
$\dot{p}_t$ = actual rate of change in prices
and $u_1, u_2, u_3$ are random error terms

Apart from testing Fisher's two hypotheses independently and in a unified framework, the model would take into account one of the simplest types of errors that might have blurred the observed price expectation variable. In the process we also get much more precise estimates of the lag structure than those obtained by Turnovsky (1970).

In two recent papers Jacob Frenkel (1975a,b) has presented a theory of the formation of short-term expectations which combines both regressive and adaptive elements. I have tested the hypothesis against the available data and incorporated it in the above structural model.

The plan of this paper is as follows: Section I contains some statistical preliminaries and some notes on the formation of expectations. Section II analyzes the results and Section III discusses a possible break in the structural relations around 1960. Finally, concluding remarks are given in Section IV.

## I. Data and the Formation of Expectations

From Livingston's survey two series of expected prices can be obtained—one from six months ahead (short term) and the other from twelve months ahead (long term) predictions of the price level. Since both Gibson and Pyle found the coefficients of the 6-month price expectations to be particularly low, this study has been restricted to the estimation of Fisher effect with short-term price expectations only. Data on market yields on 6-month bills were not available prior to 1959; hence yields on 3-month bills were used for the period 1952–70. The 6-month yield observations are monthly averages for June and December.

The basic time interval is one quarter. The following notations are used:

$p_6^*(t)$ = expected percentage price change at time t for the next six months
$p_{12}^*(t)$ = expected percentage price change at time t for the next twelve months
$\dot{p}_t'$ = actual percentage price change

for quarter immediately preceding time t

$\dot{p}_t$ = actual percentage price change for the six months immediately preceding time t
$= \frac{1}{2}(\dot{p}'_t + \dot{p}'_{t-1})$

All quantities are expressed as annual rates and past price changes are based on the Consumer Price Index.

Turnovsky tested three expectation hypotheses: unrestricted distributed lag, adaptive, and extrapolative. For the short-term expectations the equations are:

$$(9) \qquad \overset{*}{p}_6(t) = \sum_{i=0}^{\infty} w_i p_{t-i}$$

$$(10) \qquad \overset{*}{p}_6(t) = w_0 + w_1 \overset{*}{p}_6(t-2) + w_2 \dot{p}_t$$

$$(11) \qquad \overset{*}{p}_6(t) = w_0 + w_1 \dot{p}_t + w_2(\dot{p}_t - \dot{p}_{t-2})$$

The coefficient $w_1 + w_2 = 1$ and $w_0 = 0$ in equation (10) would give the original version of adaptive expectations. On the other hand, the original version of extrapolative hypothesis stipulated $w_0 = 0$ and $w_1 = 1$ in equation (11). The coefficient $w_2 < 1$ in (10) implies expectations to be regressive.

Frenkel (1975a,b) has developed a unified theory of the formation of expectations which tries to explain the impact of money supply on nominal interest rates in the short run as well as in the intermediate and the long run. Specifically he hypothesized that short-term expectations are influenced by two factors: (i) a regressive element, which is determined by the discrepancy between the actual rate of inflation $\dot{p}_t$ and an average long-term expected rate; and (ii) the usual adaptive element which is determined by the discrepancy between $\dot{p}_t$ and the expected short-term rate.

Frenkel gives a numerical example to explain the first element: consider a steady state in which all expectations are realized, and the actual and expected rates of inflation are 10 percent per unit of time. Now, consider a sudden jump in the rate of inflation to 15 percent per unit of time. Since individuals believe on the basis of past history that the average normal rate of inflation is 10 percent, they will expect the rate of inflation for the next unit of time to be below 10 percent, say, 5 percent, so as to average out to the normal mean rate of 10 percent and thus to conform with their expectations on future price level. They might, in addition, revise their expected path of prices and thus their average long-term expectation slightly upwards, in which case they will expect the rate of inflation for the immediate next period to be above 5 percent but still below 10 percent. Regarding the second element, it is assumed that whenever the actual rate of inflation exceeds the expected short-term rate, individuals will revise their short-term expectations upwards by some constant multiple of the discrepancy.

To test the above hypothesis we estimated equations of the following form:

$$(12) \qquad \overset{*}{p}_6(t) = w_0 + w_1 \overset{*}{p}_{12}(t) + w_2 \overset{*}{p}_6(t-2) + w_3 \dot{p}_t$$

The coefficient $w_1$ gives the coefficient corresponding to the regressive element and $(1 - w_2)$ would give the coefficient corresponding to the adaptive element. Thus Frenkel's hypothesis can be tested by introducing long-term expectations as an additional variable in the adaptive hypothesis given in equation (10).

## II. The Results

Ordinary least squares regression of $rn_t$ on $p_6^*(t)$ for the period 1952–70 produced the following results:

$$rn_t = \underset{(.182)}{2.347} + \underset{(.063)}{0.586} \overset{*}{p}_6(t)$$

$$D\text{-}W = 1.449 \qquad \bar{R}^2 = 0.702$$

TABLE 1—ORDINARY LEAST SQUARES TO EXPLAIN THE FORMATION OF EXPECTATIONS 1952–70

| Expectations | $\bar{R}^2$ | D-W |
|---|---|---|
| Weighted Expectations: | | |
| $p_6^*(t)=.251\dot{p}_t+.102\dot{p}_{t-1}+.543\dot{p}_{t-2}$ | .587 | 1.018 |
| (.361) (.389) (.195) | | |
| Adaptive Expectations: | | |
| $p_6^*(t)=.426\dot{p}_t+.534p_6^*(t-2)$ | .580 | 1.989 |
| (.145) (.164) | | |
| Extrapolative Expectations: | | |
| $p_6^*(t)=-.494+1.011\dot{p}_t-.568(\dot{p}_t-\dot{p}_{t-2})$ | .555 | 1.354 |
| (419) (.148) (.183) | | |
| Frenkel's Hypothesis: | | |
| $p_6^*(t)=.786p_{12}^*(t)+.046\dot{p}_t+.535p_6^*(t-2)$ | .668 | 1.962 |
| (.251) (.177) (.145) | | |

*Note*: Standard errors are in parentheses; $\bar{R}^2$ is adjusted $R^2$, and *D-W* is the Durbin-Watson statistic.

Regression results of the four hypotheses to explain the formation of expectations are given in Table 1. The results are very similar to those obtained by Turnovsky though in this case the unrestricted distributed lag model is slightly better than the adaptive and the extrapolative models on the $\bar{R}^2$ criterion. In almost all the cases the constants were found to be insignificant and were accordingly dropped. Since the coefficient of $\dot{p}_t$ in the extrapolative case and the sum of the coefficients of $\dot{p}_t$ and $\dot{p}_6(t-2)$ in the adaptive case were very close to unity, the original versions of these models were found to be successful in explaining the data. Apart from that, a negative coefficient value for $(\dot{p}_t-\dot{p}_{t-2})$ suggests strong regressivity. The introduction of $p_{12}^*$ in equation (12) was found to be a very significant additional variable. The $\bar{R}^2$ was significantly higher and the value of *D-W* statistic was very close to 2. If $p_{12}^*(t)$ can roughly be assumed to represent the (long-term) expected average rate of inflation, then the significance of the coefficient for $p_{12}^*(t)$ implies regressivity corresponding to longer-term expectations. The coefficient of the lagged short-term expectation retained the same value as in the pure adaptive model. The low value for the coefficient of $\dot{p}_t$ is only expected since it really measures the difference between the coefficients corresponding to short-term and long-term adjustments. Thus, it seems that Frenkel's (1975a,b) hypothesis best explains the observed data on price expectations.

The reduced form of the structural model (6)–(8) is

$$p_6^*(t) = \sum_{k=1}^{k} w_k\dot{p}_{t-k} + u_{1t} + u_{3t} \tag{13}$$

$$rn_t = \alpha + \beta \sum_{k=1}^{k} w_k\dot{p}_{t-k} + u_{2t} + \beta u_{3t} \tag{14}$$

This can also be written in the following alternative structural form:

$$p_6^*(t) = \sum_{k=1}^{k} w_k\dot{p}_{t-k} + u_{1t} + u_{3t} \tag{15}$$

$$rn_t = \alpha + \beta p_6^*(t) + u_{2t} - \beta u_{1t} \tag{16}$$

Let $u_{1t}+u_3t=v_{1t}$ and $u_{2t}-\beta u_{1t}=v_{2t}$. Gibson and Pyle estimated the equation (16) by ordinary least squares (*OLS*) where $p_6^*(t)$ is really endogenous. Turnovsky estimated equations of the form (15). Though measurement error in the dependent variable does not lead to any bias in *OLS* estimates, the presence of the composite disturbance term $v_{1t}$ may unnecessarily produce large standard errors of estimates. This would

[a] Standard errors are in parentheses.
[b] The constant term $w_0$ was estimated only in the extrapolative case; in other cases constants were found to be insignificant and were accordingly dropped.
[c] This is an estimate of $\alpha+\beta w_0$.

particularly be the case if $\dot{p}_{t-i}$ are correlated.

To obtain consistent estimates of $\alpha$ and $\beta$, the two-stage least squares (*2SLS*) procedure was used. The results are given in Table 2 where it is found that the estimated value of $\beta$ has increased from .586 to as high as .906 in some cases. As expected, some loss in efficiency is noticeable since the standard errors have increased uniformly. Since a consistent estimate of of the variance-covariance matrix of residuals showed rather high negative value for the covariance term, I computed the "full information" estimates. These are reported in Table 3.

The standard errors for all the coefficients have decreased considerably. The three-stage least squares (*3SLS*) estimates of $\beta$, though on the average little less than the corresponding *2SLS* estimates, were appreciably higher than the *OLS* estimates. By comparing Tables 1 and 3, it can be seen that much more precise estimates of the lag structures in the formation of price expectations have been obtained.[1]

[1] Since with twelve-month ahead predictions the estimated Fisher effects were quite sensible, I did not introduce any possible error in $\dot{p}^*_{12}$. Also, I assumed that the decision makers respond according to $\dot{p}^*_6(t-2)$ directly. In short, I did not introduce possible errors in the variables $\dot{p}^*_6(t-2)$ and $\dot{p}^*_{12}(t)$ in equations (14) and (16), respectively.

It may be noted that Gordon's approach to develop an independent measure of the lag structure was to estimate equation (14) of the reduced form and to pick up the estimated coefficients of the lagged prices. By *OLS* we obtain the following estimate of equation (14).

$$\underset{}{rn_t} = \underset{(.202)}{1.562} + \underset{(.187)}{.467}\dot{p}_t - \underset{(.198)}{.049}\dot{p}_{t-1} + \underset{(.103)}{.406}\dot{p}_{t-2}$$

Since the $var(u_2+bu_3)$ was 0.56, which is far less than $var(u_1+u_3)$, (which is 2.22), and since the true value of $\beta$ is very close to unity, the lag structure developed in this way is much more precise than that obtained from equation (13). These estimates are strikingly similar to those obtained by *3SLS*.

The estimates of error variances of the original structural model (6)–(8) are given in Table 4. Given the estimates of $var(v_1)$,

TABLE 4—ESTIMATES OF THE ERROR VARIANCES OF THE STRUCTURAL MODEL
1952–70[a]

| Expectations | $V(u_1)$ | $V(u_2)$ | $V(u_3)$ |
|---|---|---|---|
| Weighted | 1.561 | .032 | .656 |
| Adaptive | 1.393 | .166 | .871 |
| Extrapolative | 1.435 | .082 | .897 |
| Frenkel's | 1.152 | .304 | .704 |

[a] Under additional assumption that $cov(u_i, u_j)=0$, $i,j=1,2,3; i\neq j$.

$var(v_2)$, and $cov(v_1, v_2)$, one can recover only three second-order moments of the structural disturbances $(u_1, u_2, u_3)$. The three variances viz. $var(u_1)$, $var(u_2)$, and $var(u_3)$ have been estimated under additional assumptions that $cov(u_i, u_j)=0$ for $i \neq j$, $i, j, = 1, 2, 3$. Though there is no way to test these assumptions, there is some indirect evidence which suggests that the assumptions may be roughly true. Note that the assumptions

$$cov\ (u_i, u_j) = 0 \qquad i, j = 1, 2, 3, \quad i \neq j$$

would imply the following three independent restrictions:

$$(17) \qquad var\ (v_1) = E[v_1^2(t)] = \sigma_1^2 + \sigma_3^2$$

$$(18) \qquad var\ (v_2) = E[v_2^2(t)] = \sigma_2^2 + \hat{\beta}^2 \sigma_1^2$$

$$(19) \quad cov\ (v_1, v_2) = E[v_1(t), v_2(t)] = -\hat{\beta}\sigma_1^2$$

Thus, $cov(v_1, v_2)$ must have a sign opposite to that of $\beta$. Since in our case $\beta$ is always positive, equation (19) implies that $cov(v_1, v_2)$ assumes negative values. This, then, would give a positive $\sigma_1^2$. Similarly, given that $\sigma_2^2$ and $\sigma_3^2$ are positive quantities we get two additional restrictions. In all the experiments these restrictions were always satisfied. In addition, the reduced form covariance $\beta_1\ var(u_3)$ was always positive.

To the extent we can rely on these estimates, the calculations suggest that $var(u_1)$ is quite large, followed by the disturbance term in the expectation formation equation. In all the cases the error variance of the interest rate equation was found to be quite low.

### III. Structural Change Around 1960

The structural model (6)–(8) is particularly suitable for an analysis of possible changes in one or more of the structural relations. William Yohe and Denis Karnosky when relating nominal interest rates to distributed lag of past prices found enough evidence to support a break in the sample around 1960. They attributed the break to a shift in the interest rate equation. But, as Gibson has pointed out, there is also the other possibility that the shift had occurred in the formation of price expectations equation. In fact, the latter possibility has been supported by the experiments reported by Turnovsky.

Gibson found a break in the context of the equation (16); Turnovsky found the same in the contxt of equation (15). But it is interesting to note that the observed break may be due to a break in relation (6). Also, if the reduced form relation (14) does not show any break in the sample, then this finding should suggest that the shifts in relation (15) and (16) are due to shift in the relation (6), and not due to shifts in relations (7) and (8). I tested the propositions with the help of all the four expectations-formation hypotheses (9)–(12). When "extrapolative" and "distributed-lag" hypotheses were used, the Chow tests for stability of the coefficients were resoundingly rejected against the alternative that there was a break by the end of 1959. However, with "adaptive expectations," the equality of regressions hypothesis was accepted at both the 1 and 5 percent level of significance, while with Frenkel's hypothesis it was accepted only at 1 percent level. Thus, it seems that the adaptive expectations hypothesis is quite successful in explaining the reduced form interest rate equation (14) for the whole period, 1952–70.

It may seem that with the help of the adaptive expectations hypothesis the observed breaks in equations (15) and (16) can be explained by a break in the equation (6). To test a simple proposition that there was a parallel shift in the relation (6) after 1960, I estimated the whole model (6)–(8) after introducing a (0–1) dummy variable in equation (6). The coefficients appeared with right signs and the value of $\beta$ was 0.944. But the improvement in the fit on $\overline{R}^2$ criterion was only

marginal; it was apparent that the introduction of the dummy variable was not adequate to explain the shift in equation (6).

With extrapolative and distributed-lag hypotheses, there is of course the real possibility that the break occurred in both the relations (7) and (8) around 1960. Accordingly, we estimated the model with all the four hypotheses on the formation of expectations for the periods 1952–59 and 1960–70 separately.[2] The estimates were very similar to those obtained by Gibson (1972) and Turnovsky (1970); and support the hypothesis that after 1960 people have become more conscious in forming their price expectations and relating them to nominal interest rates.

## IV. Conclusions

Without being unduly repetitive, I will close by indicating briefly what I believe to be the main conclusions that can be drawn from the material presented.

### *A*

To avoid certain problems associated with the use of a deterministic distributed lag function of past prices as an observable proxy for inflationary expectations, Gibson and Pyle used some survey data on price expectations. To substantiate the speculation that the data may contain errors, I proposed an Unobservable Variable Model which accommodates not only some errors in measurement but also the presence of stochastic error term in the distributed lag function determining the unobservable variable. Evidence was found that the data on short-term expectations contain substantial error in measurement. This explains why both Gibson and Pyle obtained such low values for the coefficient corresponding to the price speculations variable in the Fisher equation.

### *B*

The evidence that observed price expectations data contain errors does not render them unusable. Occasional abrupt changes in price expectations can best be "tracked" by such data. The unobservable variable model, by a judicious use of both the observed price expectations data and the distributed lag proxy, produces many precise and sensible estimates of all the structural parameters.

### *C*

Turnovsky used the same data to test three hypotheses on the formation of price expectations in terms of past prices. In the context of my structural model more precise estimation of individual parameters were possible.

### *D*

Frenkel (1975a,b) has proposed a unified theory on the formation of short-term expectations which is supposed to be consistent with the empirical evidence on the effects of monetary expansion in the short run as well as in the intermediate and long run. It is alleged that Cagan's model of inflationary process does not explain the transitory period between two long-run equilibrium situations. In Frenkel's formulation, short-term expectations are determined by both regressive and adaptive elements. We found that the hypothesis explains the available data better than the other three hypotheses considered by Turnovsky. The short-term expectations alone explain more than 70 percent of the variations in the nominal interest rate. Though some effects of price expectations on real rate can never be overemphasized, I did not pursue that point in this paper.

[2] While estimating the model for the subperiod 1960–70, I also used the 6-month Treasury Bill rates in place of 3-month rates. The results were not found to be significantly different.

### E

My calculations support earlier findings by Gibson and Turnovsky that both the interest rate equation and the expectations formation equation had a structural break around 1960. Yohe and Karnosky found the same in the context of their regressions of nominal interest rates on distributed lag of past prices. However, when I used the adaptive expectations hypothesis, the Chow test of equality of regressions did not support a break in the reduced form interest rate equation.

# A Model of the Supply of Bilateral Foreign Aid

By LEONARD DUDLEY AND CLAUDE MONTMARQUETTE*

Despite the attention that has been paid to foreign aid in recent years, there has been very little empirical research to explain actual transfers of public funds between donors and recipients. Many authors have indeed discussed the possible motives of donor countries[1] in granting aid, but most empirical work has been directed either toward estimating aid needs or toward assessing the impact of aid on recipient countries. This study approaches the question by considering aid as a good which is consumed indirectly by the residents of the *donor* country. The supply of foreign aid is then explained by the *demand* by the donor country for the impact its aid has on the recipient country. The first step is to develop a model based on the utility function of decision makers of the donor country. This model is then applied to the 1970 aid commitments of fifteen countries belonging to the Development Assistance Committee of the Organization for Economic Cooperation and Development (*OECD*).

* Université de Montréal. Research for this study was financed by grants from the Canada Council (S72-2248) and from the Quebec Ministry of Education. Pierre Bélanger, Gilbert Boileau, and Robert Dépatie undertook a preliminary exploration of the subject in an undergraduate course paper. The computer program for Probit Analysis was supplied by John G. Cragg. We would like to thank M. G. Dagenais for helpful suggestions and Francine Brisson, Assame Diop, Aimé Gogué, and Roger Pruneau for their assistance in conducting the research. Remaining errors are the sole responsibility of the authors.

[1] I. M. D. Little and J. M. Clifford, Raymond Mikesell, George Abbott, Keith Griffin and John Enos, and Janos Horvath have all suggested several possible motives for giving foreign aid: political and economic considerations as well as the simple desire to help the less fortunate.

## I. Motives for the Supply of Foreign Aid

The question of why aid is given is not as easily answered as it might once have been. As recently as 1960, for example, the bilateral aid of the United States, France, and the United Kingdom accounted for over 80 percent of the total flow of bilateral and multilateral aid. One might have been tempted to summarize the reasons for this aid in two terms: cold war and colonialism. Ten years later, however, this share had fallen to about 50 percent of the total, as the aid of the three major donors stagnated while other countries whose political motives were perhaps less overt increased their aid rapidly. Here then is an economic phenomenon to be explained.

But the analysis of foreign aid flows is not simply an academic exercise. The end results of this aid-granting process could scarcely be considered equitable, with a number of moderately prosperous developing countries receiving 20 to 100 times as much aid per capita in 1970 as a number of other extremely poor countries. If the equitable distribution of aid may be taken as an objective, then a necessary starting point is the explanation of the present complex network of bilateral aid flows.

One characteristic of foreign aid flows which has been noted previously is what the *OECD* (p. 178) has referred to as the "small country effect"; that is, the marked tendency for small countries to receive more aid per capita than large countries. The *OECD* estimated that between 1960 and 1967 the eighty-two developing coun-

tries it covered received \$23.7 million per country plus an additional \$1.90 for each resident. In attempting to explain this bias, the *OECD* pointed to the greater openness of small countries and their consequently greater requirements of aid for financing their imports. In short, the bias toward small countries was seen as a demand phenomenon, explained by their higher aid needs.

It must be realized, however, that the demand side is only part of the story, and that actual flows must be explained by the interaction of the aid demand of recipient countries and the aid supply of donor countries. In an empirical context, it is by no means a simple matter to identify separately each of the two sides of the relationship. As we explain below, the supply side is perhaps the easier to approach, since there exist data on foreign aid commitments, which are presumably relatively free of the influence of demand.[2] What we will try to do in this study, then, is to develop a theory of the supply of foreign aid. Our basic assumption is the following: people usually give because they expect to get something in return. What is given in return is invariably something intangible and difficult to quantify; otherwise the transfer would be called an exchange rather than a gift. But in practice very few transfers are unilateral.

At an individual level there may well be exceptions to this generalization. There may indeed exist truly altruistic people who give anonymously and who expect in return neither gratitude from the recipient nor recognition from their fellows. In society as a whole, however, casual empiricism leads us to believe that such individuals are likely to be in a minority. Therefore, any decision to transfer public funds from one society to another will probably be made for motives other than altruism.

What do people expect to get in return when they make public transfers to another society? Various authors have suggested that foreign aid is motivated by political, economic, and charitable considerations.[3] We may perhaps summarize these expectations as follows:

(i) Decision makers in the donor country may expect that the recipient nation will behave more favorably toward their country, lending its support to their national political interests.

(ii) They may expect that the recipient country will confer economic benefits on their country; for example, by buying more of the products they export.

(iii) They may expect some indication that they have had a favorable impact on the residents of the recipient country; perhaps some expression of gratitude, or simply the evidence that the lives of these people have been changed by their charity.

An important point follows: the volume of each of these return flows, whether tangible or intangible, may be supposed to depend in part on the original flow of foreign aid to the recipient. In other words the residents of the donor country may be said to consume their own aid indirectly through the effects it produces in the recipient country. We may, therefore, conclude that the supply of foreign aid will be explained by the donor country's *demand* for foreign aid impact. The next step is to develop a theoretical structure for the supply of foreign aid, suitable for econometric analysis.

## II. Two Models of the Supply of Foreign Aid

In this section we shall consider two versions of a model of the supply of

[2] The comparison to be made is between commitment data and actual disbursement data, which presumably reflect to a much greater extent the interaction of supply and demand.

[3] See fn. 1.

foreign aid. In the first version, there will be no administrative costs. In the second version, there will be positive administrative costs.

### A. *Model 1: No Administrative Costs*

In this first version without administrative costs, we may think of the donor as simply filling out a check and mailing it to the beneficiary. Assume that there is only one good other than foreign aid. Let the decision makers of the donor country have the following utility function:

$$U = f(X, H) \tag{1}$$

where $H$ = consumption of the subjectively measured impact of foreign aid, treated as a private good,[4] and $X$ = total consumption of the other good.

Let $H$ be the sum of the impacts of the donor's aid on $m$ receiving countries

$$H = \sum_{j=1}^{m} H_j = \sum_{j=1}^{m} H(n_j, a_j, y_j) \tag{2}$$

where $H_j$ = subjectively measured impact on beneficiary $j$
$n_j$ = population of beneficiary $j$
$a_j$ = aid per capita received by country $j$
$y_j$ = per capita $GNP$ of country $j$

The impact on country $j$ will be an increasing function of $j$'s population and the per capita aid it receives, and a decreasing function of $j$'s per capita $GNP$:

$$\frac{\partial H}{\partial n_j} > 0, \qquad \frac{\partial H}{\partial a_j} > 0, \qquad \frac{\partial H}{\partial y_j} < 0$$

More specifically, let the impact function take the following form:

$$H_j = n_j^{\alpha}\left(\frac{a_j}{y_j}\right)^{\gamma} \quad 0 \leq \alpha \leq 1, \quad 0 \leq \gamma < 1 \tag{3}$$

The right side of (3) is essentially the relative impact of the aid on the beneficiary's economy weighted by that country's population. The elasticity $\alpha$ is then a measure of the distortion in the donor's perception of the impact of its aid, due to the division of the world's poor into countries of different size (in terms of population). If $\alpha = 1$, the "impact" of aid in each country is weighted by that country's population (no distortion); if $\alpha = 0$, the impacts are simply added without any weighting (complete distortion); if $0 < \alpha < 1$ distortion is only partial. As for the elasticity $\gamma$, it is an indication of the extent of decreasing returns in the creation of impact. Note that if $\gamma = 1$ there are constant returns, and therefore no reason why the donor should not give all its aid to a single poor country.[5]

Finally, the donor country is limited by its budget constraint

$$X + \sum_{j=1}^{m} n_j a_j = Y \tag{4}$$

where $Y = GNP$ of donor.

The maximization of $U$ subject to equations (2), (3), and (4) yields the following first-order condition:

$$\frac{f_j}{f_x} = \frac{y_j^{\gamma} n_j^{1-\alpha}}{\gamma a_j^{\gamma-1}} \tag{5}$$

[4] An alternative formulation which we have explored is to treat aid as a public good. In this case, the utility function (1) becomes that of the individual resident of the donor country, who consumes his share of the private good plus *all* of the public good, foreign aid impact. When incomes are unequal, the median voter decides in effect for everybody. The implication of this approach is that other things being equal, a larger donor should give less aid per capita than a smaller donor since the cost of the public good is shared by a greater number of taxpayers. However, the statistical results—in particular, the sensitivity of the constant term in equation (19) below to the donor's population—did not support the public good hypothesis. For simplicity, therefore, we present the argument in its private good version only.

[5] It will be noted that $\partial^2 H_j/\partial y_j^2$ is nonnegative; that is, the negative effect of an increase in income on aid impact levels off as income grows. The simplest explanation is that the charity component mentioned earlier rises increasingly sharply as income falls toward the subsistence level.

where $f_j$ and $f_x$ are the first-order partial derivatives of $U$ with respect to $H_j$ and $X$. Now the right side of equation (5) may be interpreted as the price of weighted foreign aid impact $H_j$ in terms of other goods foregone. But the weighted impact on recipient $j$ is a perfect substitute for the weighted impact of aid on any other recipient. Therefore, in equilibrium the price of weighted impact in each recipient should be identical:

$$\left(\frac{1}{\gamma}\right) a_j^{1-\gamma} y_j^{\gamma} n_j^{1-\alpha} = k, \qquad j = 1, \ldots, m$$

where $k$ is the marginal rate of substitution between aid impact and the other good. The amount of per capita aid that will be given to country $j$ is then:

$$(6) \qquad a_j = \left[\frac{\gamma k}{y^{\gamma} n_j^{1-\alpha}}\right]^{1/(1-\gamma)}$$

It should be noted that one of the characteristics of this first model is that it implies that a given donor will grant a positive amount of aid to every country.

### B. *Model 2: Positive Administrative Costs*

Consider now a somewhat more realistic version with positive administrative costs. Replace the budget constraint (4) by:

$$(7) \quad X + \left[\sum_{j=1}^{m} a_j n_j - c(a_j n_j)^{\delta}\right] = Y$$

$$0 < \delta < 1$$

where $c$ is a constant.

The second term in parentheses in equation (7) expresses the aid program's administrative costs. With $0<\delta<1$, we are assuming that these costs increase with the amount of aid, but less than proportionally.

Maximizing (1) subject to (2), (3), and (7) now yields:

$$(8) \quad a_j^{1-\gamma} + c\delta n_j^{\delta-1} a_j^{\delta-\gamma} - k\gamma n_j^{\alpha-1} y_j^{-\gamma} = 0$$

To simplify the algebra assume that $\delta$, the elasticity of these costs in relation to the amount of aid, takes on the same value as $\gamma$, the parameter which expresses the decreasing returns in the creation of impact. In this case, the solution of (8) is:

$$(9) \quad a_j = (k\gamma n_j^{\alpha-1} y_j^{-\gamma} - c\gamma n_j^{\gamma-1})^{1/(1-\gamma)}$$

The amount of aid granted will be positive if the expression in parentheses in equation (9) is positive; that is, if

$$(10) \qquad n_j^{\alpha-\gamma} > c y_j^{\gamma}/k$$

If the scale elasticity is small compared to the distortion parameter ($\delta=\gamma<\alpha$), the amount of aid will be zero for populations smaller than

$$n_1 \equiv (c y_j^{\gamma}/k)^{1/(\alpha-\gamma)}$$

and positive for larger populations.

Moreover, the right side of equation (9) reaches a maximum at

$$n_2 \equiv n_1[(1-\gamma)/(1-\alpha)]^{1/(\alpha-\gamma)}$$

The amount of aid per capita will thus be zero for populations smaller than $n_1$, will rise with the beneficiary's population from $n_1$ to $n_2$, and will fall thereafter.

It should be noticed, however, that there are two other possibilities. Should the three parameters be equal ($\delta=\gamma=\alpha$), the amount of aid per capita will be a constant (possibly zero), regardless of the beneficiary's population. But if $\delta=\gamma>\alpha$, the amount of aid given will be a decreasing function of the beneficiary's population, becoming zero for populations equal to or greater than $n_1$.

The results of this section are not necessarily limited to the particular case in which $\delta=\gamma$. Provided that the cost elasticity $\delta$ is less than a critical value, no aid will be granted to countries below a certain population. Should $\delta$ be greater than this critical value no aid will be given to

countries with more than a certain population.

### C. *Some Implications of the Models*

We may summarize the implications of the two models with the help of Table 1 and Figure 1. In effect, there are two decisions which must be taken. First, there is the decision whether or not to grant aid. In model 1, this decision is always taken in the affirmative. In model 2, however, the probability that a given donor will grant any aid at all to country $j$ may depend on the country's income level and population:

$$(11) \qquad Pr\,(a_j > 0) = g(y_j, n_j)$$

The partial derivative of $g$ with respect to $n_j$ may be either positive, negative, or zero as shown in the preceding section. But condition (10) indicates that the partial derivative with respect to the beneficiary's income level is negative:

$$(12) \qquad \partial g/\partial y_j < 0$$

TABLE 1—PROBABILITY OF GRANTING AID AND EFFECT OF RECIPIENT'S POPULATION ON THIS PROBABILITY AND ON AMOUNT GRANTED[a]

| Model | $Pr\ g=(a_j>0)$ | $\partial g/\partial n_j$ | $\partial a_j/\partial n_j \mid a_j>0$ |
|---|---|---|---|
| *Model 1* | 1 | 0 | – |
| *Model 2* | | | |
| (i) $\delta=\gamma<\alpha$ | $0<g<1$ | + | ± |
| (ii) $\delta=\gamma=\alpha$ | $g=0$ or $g=1$ | 0 | 0 |
| (iii) $\delta=\gamma>\alpha$ | $0<g<1$ | – | – |

[a] $a_j$=per capita aid granted to country $j$
$n_j$=population of recipient $j$
$\alpha$=elasticity of aid impact with respect to recipient's population
$\gamma$=elasticity of aid impact with respect to aid as proportion of recipient's *GNP*
$\delta$=elasticity of administrative costs with respect to amount of aid granted

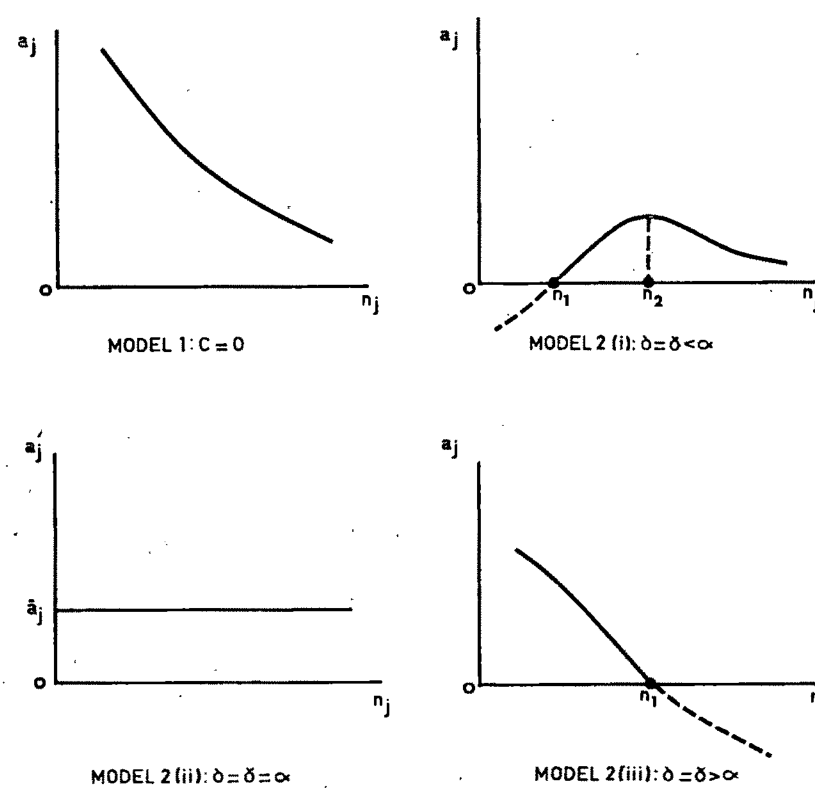

FIGURE 1. EFFECT OF RECIPIENT'S POPULATION ON PER CAPITA AID GRANTED

Given that aid will be granted to country $j$, the question is then how much to give. Model 1 answers this question with equation (6). Model 2 uses a more complicated formula given by equation (9). If $\delta=\gamma=<\alpha$, however, it may be seen that beyond the maximum at $n_2$, equation (9) approaches equation (6). We may therefore use equation (6) to explain the amount of aid granted, if this amount is positive, noting that in the case of model 2 the amount of aid need not necessarily decrease with the beneficiary's population.

### D. *Auxiliary Variables*

There are a number of factors other than the ratio of aid to $GNP$ which might be expected to have an effect on the impact of foreign aid in the recipient country, as perceived by the donor. For example, one factor is the existence of previous political ties between the two countries. One would expect that where these ties exist, a given level of aid would have a greater political impact than where no ties exist. Similarly, one might expect the economic returns to the donor from a given amount of aid to be greater where there are already economic links between the two countries. Finally, there might be a "bandwagon effect" whereby the donor's residents give a higher evaluation to the impact of their aid, the greater the aid the rest of the world gives to the recipient country. This effect would be analogous to Harvey Leibenstein's bandwagon effect.

These changes may be incorporated into the production function for impact, equation (3).

$$H_j = n_j^{\alpha}\left[\frac{a_j}{y_j}\right]^{\gamma}(e_j+1)^{\mu}w_j^{\phi}\prod_{i=1}^{r}C_i^{Z_i} \tag{13}$$

where $Z_i=0$, if there are no political links of type $i$ between donor and receiver, $i=1,\ldots,r$

$Z_i=1$, if there are political links of type $i$, $i=1,\ldots,r$

$e_j=$ previous year's exports of the donor to recipient $j$, per capita of $j$

$w_j=$ aid of the rest of the world to country $j$

In model 2, these auxiliary variables will affect the probability of granting aid. Equation (11) becomes

$$Pr\,(a_j>0) = g(y_j, e_j, w_j, Z_1, \ldots, Z_r) \tag{14}$$

where

$$\partial g/e_j>0,\quad \partial g/\partial w_j>0,\quad \partial g/\partial Z_i>0,\quad i=1,\ldots,r \tag{15}$$

The auxiliary variables will also affect the amount of aid given. Equation (6) must be replaced by

$$a_j = \left[\frac{k\gamma(e_j+1)^{\mu}w_j^{\phi}\prod_{i=1}^{r}C_i^{Z_i}}{y_j^{\gamma}n_j^{1-\alpha}}\right]^{1/(1-\gamma)} \tag{16}$$

In the light of the above discussion, we would expect the following values for the parameters of equation (16):

$$0\le\gamma<1,\quad \mu>0,\quad 0\le\alpha\le1,\quad \phi>0,\quad C_i>1,\quad i=1,\ldots,r \tag{17}$$

All that remains now is to develop a specification convenient for empirical estimation. First there is the decision whether or not to give aid. We replace equation (14) by:

$$A_j = b_0+\overset{-}{b}_1\,ln\,y_j+\overset{?}{b}_2\,ln\,n_j + \overset{+}{b}_3\,ln\,(e_j+1)+\overset{+}{b}_4\,ln\,w_j + \sum_{i=1}^{r}\overset{+*}{b}_iZ_i+\omega_j \tag{18}$$

where $A_j=0$ if no aid is given to country $j$, $A_j=1$ if aid is given to country $j$, and $\omega_j$ is a random disturbance. Expected signs for the coefficients of (18) are derived from conditions (12) and (15).

Turning now to the amount of aid to be given once the recipients have been chosen, we may take the natural logarithm of equation (16) and add an error term:

$$(19)\quad \ln a_j = \beta_0 + \overset{-}{\beta}_1 \ln y_j + \overset{?}{\beta}_2 \ln n_j + \overset{+}{\beta}_3 \ln (e_j + 1) + \overset{+}{\beta}_4 \ln w_j + \sum_{i=1}^{r} \overset{+*}{\beta_i} Z_i + \epsilon_j$$

where

$$\beta_0 = \frac{\ln (k\gamma)}{1-\gamma} \quad \beta_1 = \frac{-\gamma}{1-\gamma} \quad \beta_2 = \frac{-(1-\alpha)}{(1-\gamma)}$$

$$\beta_3 = \frac{\mu}{(1-\gamma)} \quad \beta_4 = \frac{\phi}{(1-\gamma)} \quad \beta_i^* = \frac{\ln C_i}{1-\gamma}$$

$$i = 1, \ldots, r$$

$\epsilon_j$ is an error term with $E(\epsilon_j)=0$, $E(\epsilon_j^2)=\sigma^2$, for all $j$, and the expected signs of the coefficients follow from our hypotheses concerning the values of the structural parameters as presented in condition (17).

The next step is to estimate equations (18) and (19). For (18) we used probit analysis and for (19) ordinary least squares.

## III. The Data

As we have already noted, we decided to use data on (gross) commitments of foreign aid (1970). These commitment data appear to be a better proxy for foreign aid supply than the alternative disbursement data, which are more likely to represent the results of a compromise between the aid demand of recipient countries and the aid supply of donor countries. As a measure of foreign aid, we took the *OECD*'s definition of Official Development Assistance, which includes grants and those loans which have a grant equivalent of 25 percent or more of their nominal value.

A major problem was to decide which countries to include as beneficiaries for a given donor. A first decision was to eliminate colonies and dependencies from our sample, on the grounds that aid to these regions constituted an internal transfer and thus could not be explained by the same model as that used for transfers between countries. This left ninety-three independent developing countries who had received aid from one or more of the fifteen donors in our sample.

As specified in equation (13), dummy variables were used as proxies for political links between donor and recipient countries. However, the political links included varied somewhat from one donor to another. For France, the United Kingdom, and Belgium, we included dummies which specified whether or not the recipient was a former colony of the donor. For Japan and the United States, the dummy indicated whether or not the country was in Asia or in the Western Hemisphere, respectively. In the case of Canada, one dummy corresponded to former British colonial status and the other to former French colonial status. For Belgium, we also tried the dummy corresponding to former French colonial status. Finally for Australia, Denmark, Norway, and Sweden, the dummy corresponded to former British colonial status and for the Netherlands to former Belgian colonial status.

The foreign aid commitment data for 1970 are unpublished figures compiled by the *OECD*. Data on population and Gross National Product per capita in *U.S.* dollars for 1970 were taken from International Monetary Fund and World Bank Group, *Finance and Development*, 10 (March 1973). Export data for 1969 were taken from International Monetary Fund, *Direction of Trade* and are in millions of *U.S.* dollars.

## IV. Statistical Results

Our first step was to use probit analysis to estimate equation (18). The results presented in Table 2 are quite satisfac-

TABLE 2—PROBIT ANALYSIS OF THE MODEL OF THE SUPPLY OF FOREIGN AID[a]

| | Coefficient | | | | | | | | | | | Number of observations | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|

[a] The model: $A_j = b_0 + b_1 \ln y_j + b_2 \ln n_j + b_3 \ln (c_j+1) + b_4 \ln w_j + \Sigma_{i=1}^{r} b_i^* Z_i + \omega_j$.
[b] Corresponding dummy equal to one if recipient is former colony of U.K. ($b_1^*$), France ($b_2^*$), or Belgium ($b_3^*$); otherwise zero.
[c] Corresponding dummy equal to one if recipient is in Western Hemisphere ($b_4^*$) or Asia ($b_5^*$); otherwise zero.
[d] Pseudo $R$-square.
[e] Indicates coefficient significantly different from zero at the .05 level of significance; one- or two-tail test when appropriate.

tory.[6] With respect to $b_1$, $b_3$, $b_4$, and $b_i^*$, only six of the fifty-five coefficients had their sign contradicting expectations; all of them, however, were not significantly different from zero at a .05 level of significance. Of the forty-nine coefficients with the expected sign, thirty-one were significantly different from zero.

The results for the remaining coefficient $b_2$ are especially interesting since they permit us to distinguish among the two models proposed in Section II. Here, eleven of the fourteen coefficients corresponding to the beneficiary's population were significantly different from zero, all with a positive sign. These results strongly support model 2 with positive administrative costs, and seem to support subcase (i) in which the distortion parameter is relatively high—that is, the degree of distortion is relatively low.

Our next step was to estimate the reduced form represented by equation (19) by ordinary least squares. The results fall into two groups. In the first group are Japan and six small donor countries,[7] each of which had twenty-one or fewer observations. Only a few estimated coefficients were significantly different from zero (results not shown). We would suggest that the problem here was an insufficient number of degrees of freedom.

In the second group are eight larger donors, each of whom gave to at least thirty-seven countries. Here the results,

[6] We have excluded from the results West Germany for which there was only one zero observation and hence very little to explain with probit analysis.

[7] Australia, Austria, Denmark, the Netherlands, Norway, and Sweden.

TABLE 3—REDUCED FORM COEFFICIENTS FOR MODEL OF THE SUPPLY OF FOREIGN AID[a]

| | Donor | | | | | | | |
|---|---|---|---|---|---|---|---|---|

[b] Corresponding dummy equal to one if recipient is a former colony at country in parentheses; otherwise zero.
[c] Corresponding dummy equal to one if recipient is in region in parentheses; otherwise zero.
[d] Indicates coefficient significantly different from zero at the .05 level of significance; one- or two-tail test when appropriate.

presented in Table 3, are much more satisfactory. In the case of $\beta_1$, $\beta_3$, $\beta_4$, and $\beta_i^*$, twenty-one coefficients out of thirty-one were significantly different from zero, all with the correct sign. A single coefficient out of three incorrect sign coefficients was significantly different from zero. Once again the population coefficient—in this case $\beta_2$—is of special interest. It varies in sign and is significantly different from zero (with a negative sign) in only two of the eight cases. These results tend to support model 2, subcase (i) in which administrative costs were positive but increased considerably less rapidly than the amount of aid. They are thus consistent with the probit analysis.

This last set of results was then used to derive point estimates of the structural parameters and estimates of their variances, as shown in Table 4. The quality of these estimates is somewhat more difficult to interpret since, owing to the non-linear functions that relate these parameters and the least squares estimates, the estimates of the variances are only approximations.[8] In every case, however, the estimate of the parameter $\gamma$ indicates decreasing returns to scale in the creation of impact (that is, $\gamma<1$). An important result is that there is no uniform evidence of distortion in the direction of small beneficiary countries. It will be remembered that such distortion in the relative impact of aid was suggested as a possible explanation of the observed bias of aid towards small countries. Only in the case of France does the distortion param-

*Note:* Figures in parentheses are approximate standard errors only and should be interpreted with caution.
[a] Indicates coefficient significantly different from zero at .05 level of significance if estimate of standard error is correct; one- or two-tail test when appropriate.
[b] Indicates coefficient significantly different from one at .05 level of significance if estimate of standard error is correct; one- or two-tail test when appropriate.
[c] Corresponding dummy equal to one if recipient is a former colony of this country; otherwise zero.
[d] Corresponding dummy equal to one if recipient is in this region; otherwise zero.

eter $\alpha$ appear to be significantly different from unity.

How, then, does one explain the *OECD* finding of a strongly significant negative correlation between per capita aid and the population of recipient countries? We found that in numerous cases there was a negative correlation significantly different from zero between population on the one hand, and exports, aid of the rest of the world, and the political dummy variables on the other hand. Since the estimated coefficients of these variables in the reduced form presented in Table 3 are in most cases positive and significantly different from zero, it follows from specification analysis[9] that a model of foreign aid that leaves out these other variables would produce a downward-biased estimate for the coefficient of the population variable.

Among the variables which determine the level of the impact function, the economic links represented by lagged exports from donor to recipient (per capita of the latter) proved to be very important. Only for Canada and Switzerland does the parameter $\mu$ appear to be nonsignificant. The results for the bandwagon effect are less clear: in four of the eight cases the coefficient appears significantly different from zero, but in the case of France it is with a negative sign. Finally, the political links between donor and recipient proved to be highly significant.

## V. Conclusions

This paper has presented two versions of a model of the supply of foreign aid. The model attempted to explain two decisions made by the donor country. First

[9] See Henri Theil, pp. 520–602.

was the decision whether or not to grant aid to a given developing country. The model suggested that the probability of granting aid was a decreasing function of the recipient's per capita income, as well as a function of economic, political, and bandwagon considerations. The empirical results supported these hypotheses and also indicated that perhaps because of administrative costs that increase less rapidly than the amount of aid granted to a given country, the probability of granting aid increases with the potential recipient's population.

Secondly, the model attempted to explain the amount of aid granted once the decision to give to a particular country had been taken. The apparent small country bias in the granting of per capita aid which was observed in an earlier study does not seem to be due primarily to distortion on the part of donor countries in favor of recipients with small populations. Rather it would seem to be mainly a result of misspecification of the foreign aid supply model—in particular, the omission of economic, political, and bandwagon effects. Finally, there appear to be strongly decreasing returns to a donor in converting its foreign aid into impact on a given recipient country.

# Harberger's Welfare Indicator and Revealed Preference Theory

*By* W. E. DIEWERT*

In a recent article, Arnold Harberger (1971) developed a criterion for indicating whether the utility of a single consumer has increased or decreased from situation one (where prices $p^1 \equiv (p_1^1, p_2^1, \ldots, p_N^1)$ prevailed and quantities $x^1 \equiv (x_1^1, x_2^1, \ldots, x_N^1)$ were consumed) compared to situation two (where prices $p^2 \equiv (p_1^2, p_2^2, \ldots, p_N^2)$ prevailed and quantities $x^2 \equiv x_1^2, x_2^2, \ldots, x_N^2)$ were consumed). According to Harberger's (1971, p. 788) criterion, the consumer's utility or welfare has increased going from situation one to two if the following expression is positive (or welfare has decreased if it is negative):[1]

$$(1) \quad H(p^1, p^2, x^1, x^2) \equiv p^{1T}(x^2 - x^1) + \tfrac{1}{2}(p^2 - p^1)^T(x^2 - x^1)$$

Harberger develops his welfare indicator as an approximation to the true change in welfare using a Taylor series expansion,[2] but for my purposes, the derivation of his welfare indicator is irrelevant—it is the properties of the indicator itself that we will be concerned with.

The interesting thing to note about expression (1) is that it makes use of the same basic information which is used in the revealed preference theory developed by Paul Samuelson (1947, pp. 146–63) and others;[3] i.e., price and quantity information in two periods. The question then naturally arises: Is the Harberger welfare indicator consistent with the results of revealed preference theory?[4] The main purpose of this note is to answer this question.

The following proposition shows that Harberger's welfare measure has the desirable property of being antisymmetric; i.e., if the Harberger measure indicates that welfare has increased going from situation one to two, then it will also indicate that welfare has decreased going from situation two to one.

PROPOSITION 1:

$$H(p^1, p^2, x^1, x^2) \equiv -H(p^2, p^1, x^2, x^1)$$

The proof is by computation.

Given two sets of price quantity data plus the assumption of maximizing behavior,[5] we can construct Table 1 which

I would like to acknowledge my intellectual indebtedness to S. N. Afriat, and I thank G. C. Archibald, K. J. Arrow, L. J. Lau, and a referee for their valuable comments.

[1] Note that $x^T$ denotes the transpose of the column vector $x$ so that $x^T p \equiv \sum_{i=1}^N x_i p_i$ is the inner product between the vectors $x$ and $p$.

[2] Several other authors have used Taylor series expansions or quadratic approximations along with the assumption of optimizing behavior to measure changes in utility; see Arthur Bowley, Ragnar Frisch (1936, p. 27; 1938), Harold Hotelling (1938, Sec. II), Abraham Wald, John Hicks (1946, pp. 331–33), T. Kloek, and Henri Theil (1967, pp. 200–12; 1968).

[3] See Hendrik Houthakker (1950) and the earlier work by A. A. Konyus and Herman Wold (1943, 1944).

[4] Samuelson (1964) commenting on an earlier version of the Harberger (1964) methodology raised the question of its consistency with revealed preference theory:

"Simple consumer's surplus is known to be exact only in the empirically bizarre case of parallel indifference curves (where it happens to be superfluous). The ancient theory of its approximate validity remains a modern mess; but the generalized theory of revealed preference tells precisely what inferences about individual and group preferences can be derived from various ($P$, $Q$) observations." [p. 94]

[5] We are now assuming that $x^r$ is a solution to the maximization $\max_x \{f(x) : p^{rT}x \leq p^{rT}x^r, x \geq 0_N\}$ for $r = 1, 2$ where $f$ is a utility function (or production function)

TABLE 1—REVEALED PREFERENCE TABLE

| | $p^{1T}x^2 \geq p^{1T}x^1$ | $p^{1T}x^2 < p^{1T}x^1$ |
|---|---|---|
| $p^{2T}x^1 \geq p^{2T}x^2$ | **Case (i)** Zone of Indeterminancy | **Case (ii)** $x^1$ revealed preferred to $x^2$ |
| $p^{2T}x^1 < p^{2T}x^2$ | **Case (iii)** $x^2$ revealed preferred to $x^1$ | **Case (iv)** Inconsistent preferences have been revealed |

partitions the observed price quantity data into four mutually exclusive cases. The question now is: Does Harberger's welfare indicator convey the same information as the revealed preference table? Rather surprisingly, Proposition 2 below shows that Harberger's welfare indicator is entirely consistent.

PROPOSITION 2: *Harberger's welfare indicator is consistent with the weak axiom of revealed preference in the sense that if the observed price quantity data is such that cases (ii) or (iii) in the revealed preference table occur, then the Harberger indicator will correctly indicate an increase or decrease in welfare, assuming that the data were generated by utility maximizing behavior.*

Proofs of the nontrivial propositions can be found in the Appendix.

Since Proposition 2 is a rather useful result, it may be worthwhile to provide some further discussion. Sydney Afriat (1967) has shown that a slight generalization of the weak axiom of revealed preference may be stated in terms of the two *cross coefficients* $D_{12}$ and $D_{21}$:

$$(2) \qquad D_{12} \equiv (p^{1T}x^2 - p^{1T}x^1)/p^{1T}x^1$$

$$(3) \qquad D_{21} \equiv (p^{2T}x^1 - p^{2T}x^2)/p^{2T}x^2$$

which is continuous from above (so that the maximum exists) and is subject to local nonsatiation, so that solutions to the utility maximization problem will occur on the boundary of the feasible region rather than in the interior.

Afriat's property of *cyclical consistency* in the case of only two price quantity observations can be stated as: if $D_{12} \leq 0$ and $D_{21} \leq 0$, then $D_{12} = D_{21} = 0$. Thus Afriat's property rules out the case of inconsistent preferences, case (iv) in Table 1. Now from (2) and (3), we see that:

$$(4) \quad H(p^1, p^2, x^1, x^2) \equiv \tfrac{1}{2}(p^{1T}x^1)D_{12} - \tfrac{1}{2}(p^{2T}x^2)D_{21}$$

Thus Harberger's welfare indicator is precisely equal to a weighted sum of Afriat's cross coefficients and the proof of Proposition 2 becomes (perhaps) transparently obvious.

To summarize, I have shown that Harberger's welfare indicator will correctly show whether utility has increased or decreased in cases (ii) and (iii); however, if the data reveal inconsistent preferences (i.e., case (iv) occurs), then formula (1) will tell us that welfare has increased if $H(p^1, p^2, x^1, x^2) > 0$ or decreased if $H(p^1, p^2, x^1, x^2) < 0$ when in fact we should not impute any welfare change at all in view of the fact that inconsistent preferences have been revealed.[6]

Let us suppose that we rule out case (iv); that is, we make some side calculations and check whether $D_{12} < 0$ *and* $D_{21} < 0$ in which case we agree not to use formula (1) (or any formula for that matter) in order to measure welfare changes, since inconsistent preferences have been revealed.

However, ruling out case (iv), it appears at first glance that the Harberger welfare

[6] The referee makes the following valid points:

"To make a welfare comparison of two situations characterized by price and consumption vectors, the very first thing to do is consult Table 1. If cases (ii) or (iii) pertain, then an unambiguous welfare comparison can be made without any reference to a special indicator. If case (iv) pertains, then the crucial hypothesis of a single 'rational' consumer is refuted, and analysis in this vein must cease. Only if case (i) pertains, is revealed preference theory ambiguous, and is recourse necessary to a special indicator, based on special assumptions."

indicator has some rather desirable properties: it is consistent with revealed preference theory and it merely resolves the zone of indeterminancy when the data imply that we are in case (i). The following proposition shows that the Harberger indicator does not do a very good job of resolving the zone of indeterminancy.

PROPOSITION 3: *Suppose that we are in the interior of the zone of indeterminancy; i.e.,* $p^{1T}x^2 > p^{1T}x^1$ *and* $p^{2T}x^1 > p^{2T}x^2$. *Then Harberger's welfare indicator can be made positive or negative simply by scaling prices in either period.*[7]

Proposition 3 indicates that the resolution of the zone of indeterminancy generated by the Harberger welfare indicator is extremely unsatisfactory. However, this unsatisfactory scaling property of the Harberger indicator could be eliminated by using *normalized* prices $v^r \equiv p^r/p^{rT}x^r$ for $r=1, 2$ (i.e., prices divided by expenditure in that period) in place of the prices $p^r$. In this case

$$(5)\quad H(v^1, v^2, x^1, x^2) = H(p^1/p^{1T}x^1, p^2/p^{2T}x^2, x^1, x^2) = \tfrac{1}{2}[v^{1T}x^2 - 1] - \tfrac{1}{2}[v^{2T}x^1 - 1] = \tfrac{1}{2}D_{12} - \tfrac{1}{2}D_{21}$$

and the *normalized Harberger welfare indicator* defined by (5) is independent of the scaling of prices.

Now, let us relate the normalized Harberger measure of welfare change to Hicks' (1946, pp. 330–33) measure of consumer surplus which he defines to be one half of the equivalent variation plus one half of the compensating variation. If we translate Hicks' infinitesimal changes into finite differences, we find that Hicks' measure of consumer surplus $\hat{H}$ is defined as:

$$(6)\quad \hat{H}(p^1, p^2, x^1, x^2) \equiv x^{1T}(p^2 - p^1) + \tfrac{1}{2}(x^2 - x^1)^T(p^2 - p^1) = H(x^1, x^2, p^1, p^2)$$

Thus the Hicksian measure of consumer surplus is of the same general form as Harberger's welfare indicator, except that the role of prices and quantities has been interchanged.

The following proposition shows that any result which can be obtained with respect to the normalized Harberger measure of welfare change has an exact counterpart with respect to the normalized Hicksian measure of welfare change.

PROPOSITION 4: *Hicks' normalized welfare indicator is equal to the negative of Harberger's normalized welfare indicator; i.e.,* $\hat{H}(v^1, v^2, x^1, x^2) \equiv -H(v^1, v^2, x^1, x^2)$.

The proof is by computation.

Suppose that the consumer's true utility function (or the producer's true production function in the context of an *output* indicator) can be represented by some function of $N$ variables, $f(x)$ say. Then we will say that a welfare indicator is *exact* if it correctly determines whether welfare has increased, decreased, or remained constant moving from price quantity situation one to two, relative to the true utility function $f(x)$. Note that exactness is an ordinal property. The following propositions show that the normalized Harberger welfare indicator defined by (5) is much more satisfactory than the unnormalized indicator defined by (1).[8]

[7] Harberger (1971) recognizes that normalized prices should perhaps be used in an inflationary setting: "My own preference as to a conventional way of correcting for changes in the absolute price level is to normalize on net national product = national income" (p. 793).

[8] Note that the normalized indicator defined by (5) will still have the desirable properties given in Propositions 1 and 2 but it will no longer have the undesirable property given by Proposition 3.

PROPOSITION 5: *The normalized Harberger welfare indicator defined by (5) is exact if the true utility function $f(x)$ is a once differentiable monotone transformation of the homogeneous quadratic utility function*

$$x^T Ax \equiv \sum_{i=1}^{N}\sum_{j=1}^{N} a_{ij}x_ix_j$$

*where $a_{ij}=a_{ji}$; i.e., if $f(x)=\hat{g}(x^TAx)$ where $\hat{g}'(z)\equiv d\hat{g}(z)/dz>0$.*

Assume that the consumer maximizes $f(x)$ subject to the budget constraint $v^{*T}x=1$ in the normalized prices $v^*$. Then the first-order necessary conditions for this utility maximization problem yield *Wold's Identity* (1944, pp. 69–71):[9]

$$(7) \qquad v^* = \nabla f(x^*)/x^{*T}\nabla f(x^*)$$

where $x^*$ is a solution to $\max_x \{f(x): v^{*T}x=1,\ x\geq 0_N\}$ and $\nabla f(x^*)\equiv[\partial f(x^*)/\partial x_1, \partial f(x^*)/\partial x_2, \ldots, \partial f(x^*)/\partial x_N]^T$ is the gradient vector of $f$ evaluated at $x=x^*$. We may regard the vector of functions $v(x)\equiv\nabla f(x)/x^T\nabla f(x)$ as the consumer's system of inverse demand functions; that is, $v(x)$ represents the vector of normalized prices which is consistent with $x$ being a solution to the utility maximization problem $\max_z \{f(z): v^T(x)z=1,\ z\geq 0_N\}$.[10] We use Wold's Identity below.

Using the duality between direct and indirect utility functions[11] it is possible to state an analogous version of Proposition 5 in terms of the indirect utility function. Given the direct utility function $f(x)$, one defines the indirect utility function $g$ as follows:

$$(8) \quad g(v) \equiv \max_x \{f(x): v^Tx \leq 1,\ x\geq 0_N\}$$

On the other hand, given an indirect utility function satisfying certain regularity properties, one can define the corresponding direct utility function by:

$$(9) \quad f(x) \equiv \min_v \{g(v): v^Tx \leq 1,\ v\geq 0_N\}$$

The first-order necessary conditions for the minimization problem yield *Roy's Identity*, p. 222:

$$(10) \qquad x^* = \frac{\nabla g(v^*)}{v^{*T}\nabla g(v^*)} \equiv x(v^*)$$

Thus the consumer's system of utility maximizing demand functions $x(v)$ can be generated by differentiating the indirect utility function as in (10) above. We make use of Roy's Identity in the following proposition:

PROPOSITION 6: *The normalized Harberger welfare indicator defined by (5) is exact if the true indirect utility function $g(v)$ is a once differentiable monotone transform of the homogeneous quadratic indirect*[12] *utility function*

$$v^TBv \equiv \sum_{i=1}^{N}\sum_{j=1}^{N} b_{ij}v_iv_j$$

*where $b_{ij}=b_{ji}$; i.e., if $g(v)=\hat{h}(v^TBv)$ where $\hat{h}'<0$.*

[9] Actually, this identity was obtained by Hotelling (1935) and by Konyus and S. S. Byushgens, p. 155, in the case of a linear homogeneous $f$. They also derived a version of Roy's Identity in the linear homogeneous case.

[10] $x\geq 0_N$ means each component of the $N$-dimensional vector is nonnegative; $x>0_N$ means that $x\geq 0_N$ and at least one component is positive; $x\gg 0_N$ means each component of $x$ is positive.

[11] See for example Konyus and Byushgens, René Roy, Houthakker (1952), Lawrence Lau (1969), Ronald Shephard (pp. 301–05), Giora Hanoch, Afriat (1972a), and the author (1974b). Direct utility functions are assumed to be continuous, nondecreasing, and quasi concave; the corresponding indirect utility functions will be continuous, nonincreasing, and quasi convex.

[12] Note that once differentiability of the direct utility function does not necessarily imply that the indirect utility function is differentiable and vice versa. For example, suppose that the indirect utility function is given by $g(v)=1/(v^Tbb^Tv)^{1/2}$ where $b$ is a vector of positive constants. The corresponding direct utility function is a Leontief utility function where the vector $b$ represents the unit utility input-output coefficients. The Leontief utility function is not differentiable.

It is possible to show that the normalized Harberger welfare indicator bears a close relationship to Irving Fisher's ideal index number, pp. 241–42. Let us take the direct utility function $f$ to be a homogeneous quadratic which is normalized so that it is homogeneous of degree one; i.e., define[13]

$$(11) \qquad f(x) = (x^T A x)^{1/2}$$

If the matrix $A$ in (11) is nonsingular, then for positive, normalized price vectors $v$ such that $A^{-1}v > 0_N$, we can show using definition (8) that

$$(12) \qquad g(v) = (v^T A^{-1} v)^{-1/2}$$

In any case, substituting (11) into (7), we find that:

$$(13) \quad 2H(v^1, v^2, x^1, x^2) = x^{1T} A x^2 [\{1/[f(x^1)]^2\} - \{1/[f(x^2)]^2\}]$$

an expression which we will compare with an analogous expression for the *Fisher welfare indicator* defined as:

$$(14) \quad F(v^1, v^2, x^1, x^2) \equiv (v^{1T}x^2/v^{2T}x^1)^{1/2} = ([p^{1T}x^2 p^{2T}x^2]/[p^{1T}x^1 p^{2T}x^1])^{1/2}$$

The following proposition indicates that the Fisher welfare indicator has a nicer cardinal interpretation than the Harberger welfare indicator.

PROPOSITION 7 (Konyus and Byushgens (1926, pp. 167–72)): *If the true utility function can be represented by a direct utility function of the form (11),*[14] *then* $F(v^1, v^2, x^1, x^2) \equiv f(x^2)/f(x^1)$.

The above rather amazing proposition has been noted by Samuelson (1947, p. 155) and by Afriat (1972b, p. 45). The proposition enables us to *cardinally* rank correctly (using a chain index subject to a base period normalization), not only two price-quantity situations, but an arbitrary set of price-quantity situations, provided that the quantities were generated by a single consumer (or producer) maximizing a utility (or production) function of the form (11) subject to an expenditure constraint. Note that the normalized Harberger indicator cannot *cardinally* correctly rank an entire set of data even when $f$ is defined by (11) due to the fact that the magnitude of $x^{1T}Ax^2$ which occurs in (13) is generally unknown, although the normalized Harberger indicator can be used to correctly rank *ordinally* an entire set of data under the stated assumption.

Although the cardinal notion makes good sense in the context of producer theory, "ordinalists" may object to the cardinal concept in the context of consumer theory. Thus below, we prove a version of Proposition 7 that rests only on ordinal preferences. In order to do this, we must define S. Malmquist's concept of a quantity index.

First, given a utility function $f$, define $f$'s *distance function* as $D[u; x] \equiv \max_\lambda \{\lambda : f(x/\lambda) \geq u\}$. The distance function tells us by what proportion one has to deflate the given consumption vector $x$ in order to obtain a point on the utility surface indexed by $u$. In general, $f$ can be completely characterized by $D$ (see Shephard, Hanoch, and Daniel McFadden). In par-

[13] Actually $f(x) = (x^T Ax)^{1/2}$ will not generally be a nondecreasing and quasi-concave function for all $x \gg 0_N$; thus we restrict the domain of definition of $f$ to $x$ such that $x \gg 0_N$, $Ax > 0_N$, and $x$ such that if $y^T Ax = 0$, then $y^T Ay \leq 0$. This will generally imply that $A$ is a matrix with $N-1$ nonpositive eigenvalues and one positive eigenvalue with a positive eigen-vector. This functional form has been studied by Afriat (1972b, p. 45) as a utility function and by the author (1974a) as a factor requirements function (where the quasi-concavity requirement was replaced by a quasi-convexity requirement).

[14] Or by an indirect utility function of the form $g(v) = 1/(v^T Bv)^{1/2}$ where $B$ is a symmetric matrix satisfying certain regularity conditions. The proof for the indirect case is analogous.

ticular, $D[u; x]$ is linearly homogeneous, nondecreasing, and concave in the vector of variables $x$ and nonincreasing in $u$.

Now define the *Malmquist quantity index* as $Q_M(u; x^1, x^2) \equiv D[u; x^2]/D[u; x^1]$. Note that the index depends on $x^1$ (the base period quantities), $x^2$ (the current period quantities), and on the base indifference surface (indexed by $u$) onto which the points $x^1$ and $x^2$ are deflated. The following proposition is free of cardinalist taint.

PROPOSITION 8: *Let the consumer's preferences be represented by the utility function $g[f(x)]$ where $f(x) \equiv (x^TAx)^{1/2}$ satisfies the regularity conditions of footnote 13 and $g'(\lambda) > 0$ for $\lambda > 0$ so that $g$ is a monotonically increasing function of one variable. Suppose the quantity vector $x^1$ is a solution to the utility maximization problem $max_x\{g[f(x)]: p^{1T}x = p^{1T}x^1\}$ while $x^2$ is a solution to $max_x\{g[f(x)]: p^{2T}x = p^{2T}x^2\}$ and $u^1 \equiv g[f(x^1)]$, $u^2 \equiv g[f(x^2)]$. Then the Fisher welfare $F(v^1, v^2, x^1, x^2) = Q_M(u; x^1, x^2)$ (the Malmquist quantity index) for every $u$ (i.e., for any reference indifference surface).*

Propositions 7 and 8 suggest that the Fisher welfare indicator may be interpreted as a quantity index providing that the underlying aggregate $y$ has the function for $y = (x^TAx)^{1/2}$ or is a monotonic transformation of this functional form, irrespective of whether we are in the producer or consumer context. The functional form defined by (11) is "flexible" in the sense that it can provide a second-order approximation to an arbitrary twice differentiable, linear homogeneous function.[15] Thus Fisher's "ideal" index does in fact appear to be reasonably ideal and should be more widely used than it has been.[16]

Returning now to the problem of the determination of the change in welfare when there are only two price-quantity situations, the above results show that the normalized Harberger indicator (5) and the Fisher-Byushgens-Konyus indicator (14) are exact if the underlying true utility function is a monotone transform of a homogeneous quadratic direct or indirect utility function and thus has the property of homotheticity.[17] This property in turn implies that all income elasticities are unitary,[18] which is not consistent with Engel's Law. However, it turns out that the normalized Harberger welfare indicator (5) and the Fisher welfare indicator (14) are exact for functional forms which generate non-linear Engel curves.

We term the Fisher index *exact* for a set of preferences if when $x^1$ is indifferent to $x^2$, $F(v^1, v^2, x^1, x^2) = 1$ and when $x^2$ is preferred to $x^1$, $F(v^1, v^2, x^1, x^2) > 1$. It is clear from (5) and (14) that the class of preferences which is exact for the normalized Harberger welfare indicator is also exact for the Fisher indicator. A partial characterization of the class of preferences for which the Fisher indicator is exact has been provided by Byushgens. He has shown that the indifference surface generated by a differentiable $f$ which has the property: $\{f(x^1) = f(x^2)$ implies $x^{2T}\nabla f(x^1)/x^{1T}\nabla f(x^1) = x^{1T}\nabla f(x^2)/x^{2T}\nabla f(x^2)\}$ is of the form $\{x: x^TAx = 1\}$ for some symmetric matrix $A$. The following extension of Byushgens' result shows that the "quadratic" indifference surfaces can shift in a nonhomothetic manner as the utility level changes.[19]

[15] See the author (1974a) for a proof. Note that the hypothesis of linear homogeneity is essential for this proposition.

[16] Note that the Fisher-Byushgens-Konyus welfare indicator defined by (14) also has the desirable properties given in Propositions 1 and 2; in particular, the indicator is consistent with cases (ii) and (iii) of our revealed preference table.

[17] See Shephard, p. 30, for a definition.

[18] See, for example, Lau (1969, p. 393).

[19] Note that the normalized Harberger indicator is *not* exact for the quadratic utility function $a^Tx + x^TAx$ where $a$ is a nonzero vector and $A$ is a nonzero matrix.

PROPOSITION 9: *Suppose that the preferences of a consumer can be represented by the implicit quadratic distance function,*

$$D[u; x] \equiv \left( \sum_{i=1}^{N} \sum_{j=1}^{N} a_{ij}(u)x_i x_j \right)^{1/2} \equiv (x^T A(u)x)^{1/2}$$

*where* $a_{ij}(u) = a_{ji}(u)$ *and* $(u, x)$ *belongs to a set* $S \equiv \{(u, x): (x^T A(u)x)^{1/2}$ *is a nondecreasing, positive, and concave function of* $x$ *and a decreasing function of* $u\}$. *Let* $x^r$ *be a solution to the utility maximization problem* $\max_x\{f(x): p^{rT}x = p^{rT}x^r, x \geq 0_N\} \equiv u^r$ *and let* $(u^r, x^r) \in S$ *for* $r = 1, 2$ *where* $f$ *is the utility function generated by the implicit quadratic distance function.*[20] *If* $x^2$ *is sufficiently close to* $x^1$ *so that* $x^{2T}\nabla_x D[u; x^1]$ *is a decreasing function of* $u$ *for* $u$*'s in the interval between* $u^1$ *and* $u^2$, *then the Fisher and normalized Harberger indicators are exact.*

Since $D[u; x]$ is linearly homogeneous in $x$, Euler's Theorem implies that $x^{2T}\nabla_x D[u; x^1] = D[u; x^1]$ when $x^1 = x^2$. Since $D[u; x^1]$ is decreasing in $u$ by assumption, it follows that $x^{2T}\nabla_x D[u; x^1]$ will be decreasing in $u$ for $x^2$ close enough to $x^1$. In particular, if preferences are homothetic so that $A(u) \equiv A/g^{-1}(u)$ where $g^{-1}$ is an increasing function of one variable and $A$ is a symmetric matrix satisfying the conditions outlined in footnote 13, then $x^{2T}\nabla_x D[u; x^1]$ will be decreasing in $u$ for every $x^1$ and $x^2$ in the domain of definition defined in footnote 13. In any case, the hypotheses of Proposition 9 do not appear to be particularly restrictive.

It can be shown that there is a dual analogue to Proposition 9; i.e., the normalized Harberger and Fisher indicators are also exact for preferences which can be represented by the *implicit quadratic cost function* $C[u; v] \equiv (v^T B(u)v)^{1/2}$ (for $v^1$ close enough to $v^2$ so that $v^{2T}\nabla_v C[u; v^1]$ is an increasing function of $u$), where $B(u)$ is a symmetric matrix of functions which satisfies the regularity conditions of footnote 13 for each $u$, and in addition $(v^T B(u)v)^{1/2}$ is an increasing function of $u$.

Thus the normalized Harberger and the Fisher welfare indicators are exact for a certain class of nonhomothetic utility functions, and this class of functions appears to be broad enough to provide a second-order differential[21] approximation to an arbitrary twice differentiable direct utility function.

The contents of this paper can be summarized as follows: (i) Harberger's welfare indicator (1) does have some desirable properties (recall Propositions 1 and 2); (ii) in view of Proposition 3, it is better to use the normalized Harberger welfare indicator (5) (or the equivalent Fisher welfare indicator (14) since both indicators give the correct ordinal answer for the same class of preferences); (iii) the normalized Harberger indicator will give the correct answer for a surprisingly broad class of functional forms for utility functions; (iv) Irving Fisher's ideal index number can be given a rather strong economic justification; and (v) Hicks' measure of consumer surplus in finite difference form using normalized prices is equal to the negative of the (normalized) Harberger welfare change.

Although the above results do justify the use of a consumer surplus concept in empirical applications, they do not justify the addition of welfare changes across consumers without some further weighting.[22]

[20] For formal duality theorems see Hanoch, McFadden, and Shephard. The utility function $f$ which corresponds to a distance function $D$ is defined by $f(x) \equiv \max_u \{u: D[u; x] \geq 1\}$.

[21] That is, the approximating function can attain the first- and second-order partial derivatives of the function to be approximated at a given point. This terminology follows Lau (1974).

[22] Note that the consumer surplus technique cannot in general be used to *predict* what the change in welfare would be before the consumer makes his choices. In order to predict, it is necessary to assume a functional

## Appendix

*Proof of Proposition 2:*

Consider case (iii) where $x^2$ is revealed preferred to $x^1$. (The proof of case (ii) is entirely analogous and case (iv) does not occur under the assumption of utility maximizing behavior):

$$\begin{aligned} H(p^1, p^2, x^1, x^2) &= p^{1T}(x^2 - x^1) + \tfrac{1}{2}(p^2 - p^1)^T(x^2 - x^1) \\ &= \tfrac{1}{2}[p^{1T}x^2 - p^{1T}x^1] - \tfrac{1}{2}[p^{2T}x^1 - p^{2T}x^2] \\ &= \tfrac{1}{2}[\text{a nonnegative number}] \\ &\quad - \tfrac{1}{2}[\text{a negative number}] \\ &> 0 \end{aligned}$$

*Proof of Proposition 3:*

Let us scale prices in period two according to the positive number $\lambda$. Then

$$\begin{aligned} H(p^1, \lambda p^2, x^1, x^2) &= \tfrac{1}{2}[p^{1T}x^2 - p^{1T}x^1] \\ &\quad - \tfrac{1}{2}\lambda[p^{2T}x^1 - p^{2T}x^2] \\ &= \tfrac{1}{2}[\text{positive number}] \\ &\quad - \tfrac{1}{2}\lambda[\text{positive number}] \end{aligned}$$

Thus if we choose the scaling factor $\lambda$ to be small, $H>0$ and if we choose $\lambda$ to be large, then $H<0$.

*Proof of Proposition 5:*

$2H(v^1, v^2, x^1, x^2) \equiv [v^{1T}x^2-1]-[v^{2T}x^1-1]=[v^T(x^1)x^2-v^T(x^2)x^1] = \{(x^{2T}\nabla f(x^1))/(x^{1T}\nabla f(x^1))\} - \{(x^{1T}\nabla f(x^2)/(x^{2T}\nabla f(x^2))\} = \{(x^{2T}\hat{g}'(x^{1T}Ax^1) \cdot 2Ax^1)/(x^{1T}\hat{g}'(x^{1T}Ax^1)2Ax^1)\} - \{(x^{1T}\hat{g}'(x^{2T}Ax^2) \cdot 2Ax^2)/(x^{2T}\hat{g}'(x^{2T}Ax^2)2Ax^2)\} = x^{2T}Ax^1\{(1/x^{1T}Ax^1)-(1/x^{2T}Ax^2)\}$ using $A=A^T$. Since $\nabla f(x)>0_N$ and $\hat{g}'>0$, we may restrict our attention to $x\gg 0_N$ such that $Ax>0_N$. In this case, the term $x^{2T}Ax^1$ which occurs above is positive. Thus $H(v^1, v^2, x^1, x^2)>0$ is equivalent to $[1/x^{1T}Ax^1-1/x^{2T}Ax^2]>0$ which is equivalent to (since $x^{rT}Ax^r>0$): $x^{2T}Ax^2> x^{1T}Ax^1$. But since $\hat{g}'>0$, this is equivalent to $\hat{g}(x^{2T}Ax^2)=f(x^2)>f(x^1)=\hat{g}(x^{1T}Ax^1)$. Thus the normalized Harberger welfare indicator correctly indicates that utility has increased moving from the first price-quantity situation to the second. The analysis for the other cases is similar.

form for the direct or indirect utility function and use Wold's Identity (7) or Roy's Identity (10) plus standard econometric techniques in order to estimate the unknown parameters of the utility function. See Laurits Christensen, Dale Jorgenson, and Lau for an empirical application, and the author (1974b) for a review of the literature.

*Proof of Proposition 6:*

$2H(v^1, v^2, x^1, x^2) \equiv [v^{1T}x^2-1]-[v^{2T}x^1-1] = v^{1T}x(v^2)-v^{2T}x(v^1) = [v^{1T}\nabla g(v^2)/v^{2T}\nabla g(v^2)] - [v^{2T}\nabla g(v^1)/v^{1T}\nabla g(v^1)] = v^{1T}Bv^2[(1/v^{2T}Bv^2)-(1/v^{1T}Bv^1)]$ using $g(v)\equiv\hat{h}(v^TBv)$. At this stage, it is necessary to make use of the assumption that $g(v)$ is an indirect utility function, and thus it must be nonincreasing in its arguments; i.e., we assume $\nabla g(v)<0_N$. Since $\hat{h}'<0$, we restrict attention to $v\gg 0_N$ such that $Bv>0_N$ to ensure that $\nabla g(v)<0_N$. Thus the term $v^{1T}Bv^2$ which occurs above is positive and we find that $H(v^1, v^2, x^1, x^2)>0$ is equivalent to $[1/v^{2T}Bv^2-1/v^{1T}Bv^1]>0$ which is equivalent to $v^{1T}Bv^1>v^{2T}Bv^2$ and since $\hat{h}'<0$, this is equivalent to $\hat{h}(v^{2T}Bv^2)=g(v^2)>g(v^1)=\hat{h}(v^{1T}Bv^1)$. Thus the normalized Harberger welfare indicator correctly indicates that utility has increased moving from the first price-quantity situation to the second. The analysis for the other cases is similar.

*Proof of Propositon 7:*

$F(v^1, v^2, x^1,x^2)\equiv(v^{1T}x^2/v^{2T}x^1)^{1/2}=([x^{2T}\nabla f(x^1)/x^{1T}\nabla f(x^1)]/[x^{1T}\nabla f(x^2)/x^{2T}\nabla f(x^2)])^{1/2}$ using (7) $=([x^{2T}Ax^1/\{f(x^1)\}^2]/[x^{1T}Ax^2/\{f(x^2)\}^2])^{1/2}$ using $(11)=f(x^2)/f(x^1)$.

*Proof of Proposition 8:*

If we solve $g[f(x/\lambda)]=u$ for $\lambda$, we obtain the distance function, $\lambda=D[u;x]=(x^TAx)^{1/2}/g^{-1}(u)$ where $g^{-1}[g(u)]\equiv u$.

The first-order conditions for the two utility maximization problems after elimination of the Lagrange multipliers (Wold's Identity) yield the relations $v^1\equiv p^1/p^{1T}x^1=Ax^1/x^{1T}Ax^1$ and $v^2\equiv p^2/p^{2T}x^2=Ax^2/x^{2T}Ax^2$. Use these relations to eliminate $v^1$ and $v^2$ from the Fisher welfare indicator and obtain $F(v^1, v^2, x^1, x^2)\equiv(v^{1T}x^2/v^{2T}x^1)^{1/2}=[(x^{1T}Ax^2/x^{1T}Ax^1)/(x^{2T}Ax^1/x^{2T}Ax^2)]^{1/2}=(x^{2T}Ax^2)^{1/2}/(x^{1T}Ax^1)^{1/2}=[(x^{2T}Ax^2)^{1/2}/g^{-1}(u)]^{1/2}/[(x^{1T}Ax^1)^{1/2}/g^{-1}(u)]^{1/2}=D[u;x^2]/D[u;x^1]\equiv Q_M(u; x^1, x^2)$ for any $u$.

*Proof of Proposition 9:*

It is first necessary to express the partial derivatives of $D$ with respect to the components of $x$, $\nabla_x D[u^r; x^r]$; $r=1, 2$, in terms of the derivatives of $f(x)$. We have $D[u^r; x^r]=1$ for $r=1, 2$ since each $x^r$ is on the utility surface indexed by $u^r$. To determine how the distance $D[u^1; x^1]$ changes as the components of $x^1$ change, apply the implicit function theorem to the equation $f(x^1/\lambda)=u^1$ (where $\lambda=1$ initially). We find that $\partial\lambda/\partial x_j \equiv \partial D[u^1; x^1]/\partial x_j = (\partial f(x^1)/\partial x_j)/x^{1T}\nabla f(x^1)$ for $j=1, 2, \ldots, N$. Similarly, $\nabla_x D[u^2; x^2] = \nabla f(x^2)/x^{2T}\nabla f(x^2)$. Also, by Wold's Identity, $v^1 \equiv p^1/p^{1T}x^1 = \nabla f(x^1)/x^{1T}\nabla f(x^1)$ and $v^2 = \nabla f(x^2)/x^{2T}\nabla f(x^2)$. Upon noting that the right-hand sides of the last two sets of equations are equal to the right-hand sides of the earlier set, we obtain

$$\text{(A1)} \quad v^1 \equiv p^1/p^{1T}x^1 = \nabla_x D[u^1; x^1] \quad \text{and} \quad v^2 \equiv p^2/p^{2T}x^2 = \nabla_x D[u^2; x^2]$$

Now substitute equation (A1) into the Fisher indicator and we obtain $F(v^1, v^2, x^1, x^2) \equiv (v^{1T}x^2/v^{2T}x^1)^{1/2} = (x^{2T}\nabla_x D[u^1; x^1]/x^{1T}\nabla_x D[u^2: x^2])^{1/2} = (x^{2T}\nabla_x D[u^1; x^1]/[x^{1T}A(u^2)x^2/(x^{2T}A(u^2)x^2)^{1/2}])^{1/2} = (x^{2T}\nabla_x D[u^1; x^1]/[x^{2T}A(u^2)x^1])^{1/2}$ (since $D[u^2; x^2] = (x^{2T}A(u^2)x^2)^{1/2} = 1) = (x^{2T}\nabla_x D[u^1; x^1]/\{[x^{2T}A(u^2)x^1x^{1T}A(u^2)x^1]/x^{1T}A(u^2)x^1\})^{1/2} = (x^{2T}\nabla_x D[u^1; x^1]/x^{2T}\nabla_x D[u^2; x^1])^{1/2}/D[u^2; x^1]$. If $u^1 < u^2$, then $x^{2T}\nabla_x D[u^1; x^1] > x^{2T}\nabla_x D[u^2; x^1]$ since $x^{2T}\nabla_x D[u; x^1]$ is a decreasing function of $u$. Also, since $D[u, x^1]$ is decreasing in $u$, $1 = 1/D[u^1; x^1] < 1/D[u^2; x^1]$. Thus $F(v^1, v^2, x^1, x^2) > 1$. Similarly if $u^1 = u^2$, $F(v^1, v^2, x^1, x^2) = 1$ and if $u^1 > u^2$, $F(v^1, v^2, x^1, x^2) < 1$, which proves that the Fisher indicator is exact.

# The Determinants of Investment in Petroleum Reserves and Their Implications for Public Policy

*By* JAMES C. COX AND ARTHUR W. WRIGHT*

Interest in the determinants of investment in crude oil and natural gas reserves derives from three sources. First, it is always interesting to find a satisfactory explanation of investment behavior in any industry. Second, an aspect of the current concern with the "energy crisis" is the domestic crude petroleum industry's productive capacity, which is an increasing function of the stock of proved oil and gas reserves. Third, there is a decades-old controversy over the special provisions of the federal corporation income tax law which apply to petroleum producers; those special provisions have traditionally been justified by an asserted need to increase investment in petroleum reserves in order to protect "national security."[1]

In three previous papers,[2] we explored the running controversy over the special petroleum tax provisions. In our 1973a paper, we outlined a framework for determining whether the special provisions were cost effective compared to alternative policies for increasing investment in petroleum reserves.[3] We concluded that it was impossible to evaluate the policy because there were as yet no reliable estimates of the determinants of investment in petroleum reserves.

In this paper we present a model of investment in proved reserves in the *U.S.* crude petroleum producing industry, and empirical results for a subsector of that industry for 1959–71, using estimating equations derived from the model. The subsector consists of the five major petroleum producing states which practice "market-demand prorationing."[4] The empirical results indicate that investment in petroleum reserves depended on three public policies: the special federal tax provisions, state market-demand prorationing, and the federal oil import quota. It is possible to draw some tentative policy conclusions from our empirical results, al-

* Associate professors of economics, University of Massachusetts. An earlier draft of this paper was presented at the 1973 Winter Meetings of the Econometric Society. We want to thank Ronald Ehrenberg, Robert Hall, and James Kindahl for helpful advice and criticism. Valuable programming assistance was provided by Donald Barnett, Jr. Partial financial support was provided by the Ford Foundation and by the University of Massachusetts. Neither institution is responsible for the contents of this paper.

[1] The special federal tax provisions for crude petroleum producers are the option to claim "percentage" rather than "cost" depletion on producing wells, and the option to expense rather than depreciate so-called "intangible" drilling costs. Compared to uniform tax treatment of corporate income in all industries, the special provisions for petroleum are a subsidy administered through the revenue side of the budget. Other mineral industries may also claim percentage depletion. See Susan Agria for a detailed discussion of the special tax provisions for mineral industries.

[2] The authors (1973a, b), and Wright.

[3] Even a finding that the tax-subsidy policy was cost-effective in increasing petroleum reserve investment would not, of course, necessarily imply that the policy is "in the public interest," since tradeoffs with other programs would not be considered. See the authors (1975a) for a preliminary application of the cost-effectiveness approach to evaluating the special tax provisions.

[4] The five states are Kansas, Louisiana, New Mexico, Oklahoma, and Texas. According to American Petroleum Institute (*API*) et al. (1972), they contain about 75 percent of *U.S.* proved reserves outside Alaska. The operation of market-demand prorationing is discussed in detail in Sections I and IV below.

though a complete analysis of the three public policies will require additional empirical estimates.

The model is developed in Section I. The data sources and methodology used to outfit the model for empirical testing are discussed in Section II. The empirical results are reported in Section III. Finally, Section IV contains the conclusions, including the policy implications of our results.

## I. A Model of the Crude Petroleum Producer[5]

We assume that crude petroleum producers maximize the present value of after-tax cash flow, subject to the constraints of a production function and an accounting identity. The production function is assumed to be *CES*. The accounting identity relates changes in petroleum reserve stocks to flows of gross investment in reserves and current output ("depreciation").

The after-tax cash flow of a crude petroleum producer is conveniently represented as the difference between a revenue term and two cost terms, one for investment (reserve acquisition) costs and one for other input costs. Thus after-tax cash flow at time t can be written as

$$N(\mathrm{t}) = N_1(\mathrm{t}) - N_2(\mathrm{t}) - N_3(\mathrm{t}) \tag{1}$$

where $N_1$ is the revenue term and $N_2$ and $N_3$ are the investment and noninvestment cost terms, respectively. We discuss each of these cash-flow components in turn.

A crude petroleum producer must make royalty payments to the landowners from whom the drilling and production rights have been leased. These payments are customarily calculated as a percentage of gross revenue.[6] Let $(1-\pi)$ be the proportion of gross revenue which must be paid in royalty; then the proportion $\pi$ of gross revenue accrues to the producer. If $p$ is the price and $Q$ the quantity of marketed output, the revenue of a crude petroleum producer before taxes is $\pi p Q$.

The after-tax revenue of a crude petroleum producer depends on several tax provisions. State and local governments assess production and severance taxes on both quantity of production and revenue; these are represented in the after-tax cash flow equation by the average production and severance tax rate $y$. These taxes are deductible from net income subject to the federal corporation income tax, which is assessed at rate $u$. Further deductions from federal tax are allowed for a proportion $z$ of gross revenue through the percentage depletion allowance. Together, the royalty share and the tax provisions determine the after-tax revenue component of the cash flow equation at time t:

$$N_1(\mathrm{t}) = \{1 - y(\mathrm{t}) - u(\mathrm{t}) \cdot [1 - y(\mathrm{t}) - z(\mathrm{t})]\}\pi(\mathrm{t})p(\mathrm{t})Q(\mathrm{t}) \tag{2}$$

Various categories of investment cost in the crude petroleum industry are treated differently under the federal corporation income tax. Define the following terms: $I(\mathrm{t})$ is total reserve acquisition cost at time t; $q_1(I(\mathrm{t}), \mathrm{t})$ is the proportion of $I(\mathrm{t})$ spent on drilling dry holes; $q_2(I(\mathrm{t}), \mathrm{t})$ is the proportion of $I(\mathrm{t})$ spent on "intangible" costs of successful wells; $q_3(I(\mathrm{t}), \mathrm{t})$ is the proportion of $I(\mathrm{t})$ spent on "tangible" costs of successful wells; and $D(\mathrm{t})$ is the discounted value at time t of the time stream of tax deductions from one dollar of depreciable outlays made at time t. The three proportions $q_j$ sum to one at any time t.

Dry-hole costs $q_1 I$ and intangible costs

[5] In constructing the model, we have benefitted from the earlier work on investment in manufacturing by Dale Jorgenson (1965, 1967) and by Robert Hall and Jorgenson. Throughout the present paper, "petroleum" refers to crude oil, natural gas, and natural gas liquids.

[6] Stephen McDonald (1963, p. 18), explains how the royalty payment comes "off the top" before tax liability is calculated.

$q_2I$ are fully deductible from gross income in the year in which they are incurred. Tangible costs $q_3I$ must be capitalized and depreciated over a number of years; therefore the time t value of the tax deductions they provide is $Dq_3I$. Thus we have the after-tax investment cost component of the cash-flow equation at time t:

$$(3)\quad N_2(t) = \{[1-u(t)][q_1(I(t),t)+q_2(I(t),t)] + [1-u(t)D(t)]q_3(I(t),t)\}I(t)$$

Other input cost categories are also treated differently under the federal corporation income tax. Define the following terms: $L$ is an index of the quantities of nonreserve inputs into the production of crude petroleum; $w_1$ is the expensible cost per unit of $L$; $w_2$ is the depreciable cost per unit of $L$; and $w_3$ is the nondeductible cost per unit of $L$ for producers taking percentage depletion rather than cost depletion. Then the noninvestment cost component of the cash-flow equation at time t is

$$(4)\quad N_3(t) = \{[1-u(t)]w_1(t) + [1-u(t)D(t)]w_2(t) + w_3(t)\}L(t)$$

The quantity of output at time t is constrained by the differentiable implicit production function

$$(5)\quad F(Q(t), \Omega(t), L(t), t) = 0$$

The variable $\Omega$ is the full-time equivalent stock of proved reserves; we specify the proved reserves input that way instead of simply as the stock of proved reserves because of market-demand prorationing (*MDP*). *MDP* limits the use of the productive services of proved petroleum reserves. For example, the Texas Railroad Commission (*TRRC*) formerly imposed "shutdown days" on the operation of wells subject to its control.[7] Thus if there had been fifteen shutdown days in a month of thirty days, the market-demand factor $S$ would have been

$$(6)\quad S = 0.5 = \frac{30-15}{30}$$

If *MDP* were actually enforced as the name shutdown days suggests, by shutting wells down completely part of the time, the full-time equivalent of a stock of reserves $R$ would be simply $SR$; the flow of services from the stock of reserves could then be assumed proportional to $SR$. In fact, *MDP* is enforced differently; a controlled well is permitted to operate every day, so long as total output for the month does not exceed the quantity $S$ times the "rated allowable" capacity of the well (which the *TRRC* also determines). Producers may therefore choose to obtain a given flow of productive services from fewer proved reserves than if they were forced to shut down part of the time; if so, they will utilize their reserves more intensively than they would under a literal shutdown days scheme. To include this possibility, we write $\Omega$ as the function

$$(7)\quad \Omega(t) = S(t)^{\theta}R(t), \qquad 0 \leqq S(t) \leqq 1, \quad 0 < \theta$$

where $\theta$ is the elasticity of the full-time equivalent stock of reserves with respect to the market-demand factor $S$. A literal shutdown days scheme would be the special case of (7) where $\theta$ equals 1. If $\theta$ is less than 1, it would mean that prorationed producers hold a smaller stock of reserves for any flow of productive services under actual *MDP* than under literal shutdown days. A value of $\theta$ greater than 1 would have the opposite implication; this case seems unlikely, but the actual value of $\theta$ is, of course, an empirical question.

Gross additions to proved reserves at time t are represented by the differentiable function $\phi(I(t), t)$. The function $\phi$ is as-

[7] In 1963, the *TRRC* ceased using shutdown days and began setting "market demand factors" directly in percentage terms, as in statement (6). As the text indicates, the two regulatory procedures are equivalent.

sumed to be increasing and strictly concave in $I$ (expenditures on acquiring reserves) for all values of t. This representation assumes that at every point in time, as the size of the reserve acquisition program increases, the marginal addition to reserves per dollar spent decreases. This might occur, for example, if the proportion of "dry holes" increased or if the average quantity of proved reserves per successful well diminished.

Let $r(t)$ be the time-rate of change of the stock of proved reserves, $dR(t)/dt$. Then we have the accounting relation (capital stock equation of motion)

$$r(t) = \phi(I(t), t) - Q(t) \tag{8}$$

That is, the rate of change of the stock of proved reserves at time t must equal the rate of gross additions to reserves at time t less the rate of output from reserves at time t.

The assumed objective of a petroleum producer is maximization of the present value of after-tax cash flow,

$$V = \int_0^\infty N(t) e^{-\int_0^t i(s)ds} dt \tag{9}$$

where $i(s)$ is the after-tax rate of interest. The solution to the problem of maximizing (9), subject to (5), (7), and (8), can be found by maximizing the Lagrangian function

$$\int_0^\infty g(t)dt = \tag{10}$$

$$\int_0^\infty \{N(t)+\lambda(t)F(Q(t), S(t)^\theta R(t), L(t), t)$$

$$+\eta(t)[\phi(I(t), t)-Q(t)-r(t)]\} e^{-\int_0^t i(s)ds} dt$$

Substituting (1)–(4) into (10), we find the Euler necessary conditions to be equations (5) and (8), plus the following:

$$0 = \frac{\partial g(t)}{\partial Q(t)} = \lambda(t)\frac{\partial F}{\partial Q(t)} + \{1 - y(t) - u(t) \cdot [1 - y(t) - z(t)]\}\pi(t)p(t) - \eta(t) \tag{11}$$

$$0 = \frac{\partial g(t)}{\partial L(t)} = \lambda(t)\frac{\partial F}{\partial L(t)} - \{[1 - u(t)]w_1(t) + [1 - u(t)D(t)]w_2(t) + w_3(t)\} \tag{12}$$

$$\begin{aligned} 0 = \frac{\partial g(t)}{\partial I(t)} = \eta(t)\frac{\partial \phi}{\partial I(t)} &- \{[1-u(t)][q_1(I(t), t)+q_2(I(t), t)] \\ &+ [1 - u(t)D(t)]q_3(I(t), t)\} \\ &- \left\{[1 - u(t)]\left[\frac{\partial q_1}{\partial I(t)} + \frac{\partial q_2}{\partial I(t)}\right] \right. \\ &\left. + [1 - u(t)D(t)]\frac{\partial q_3}{\partial I(t)}\right\} I(t) \end{aligned} \tag{13}$$

$$\begin{aligned} 0 &= \frac{\partial g(t)}{\partial R(t)} - \frac{d}{dt}\left(\frac{\partial g(t)}{\partial r(t)}\right) \\ &= \lambda(t)S(t)^\theta \frac{\partial F}{\partial \Omega(t)} + \frac{d\eta(t)}{dt} - i(t)\eta(t) \end{aligned} \tag{14}$$

The preceding necessary conditions can be used to derive the investment functions implicit in the model. We first derive and interpret one argument of those functions, namely, the output-input, after-tax relative price variable. Then we assume a specific form of the production function to derive the investment functions; their discrete approximations comprise the estimating equations used in the empirical work.

The first step is to show that the necessary conditions imply that a petroleum producer should set the marginal product of its stock of reserves equal to the ratio of the marginal after-tax cost of holding reserves to the marginal after-tax net return from producing reserves. Using equations (5) and (7) and the implicit function theorem, we find

$$(15)\quad \frac{\partial Q(t)}{\partial R(t)} = -S(t)^{\theta}\frac{\lambda(t)\partial F/\partial\Omega(t)}{\lambda(t)\partial F/\partial Q(t)}$$

Equations (11) and (14) imply

$$(16)\quad -S(t)^{\theta}\frac{\lambda(t)\partial F/\partial\Omega(t)}{\lambda(t)\partial F/\partial Q(t)} = \frac{i(t)\eta(t) - d\eta(t)/dt}{\{1-y(t)-u(t)[1-y(t)-z(t)]\}\pi(t)p(t)-\eta(t)}$$

Equations (15) and (16) imply

$$(17)\quad \frac{\partial Q(t)}{\partial R(t)} = \left[\left\{i(t) - \frac{1}{\eta(t)}\frac{d\eta(t)}{dt}\right\}\eta(t)\right] \div [\{1-y(t)-u(t)[1-y(t)-z(t)]\}\pi(t)p(t)-\eta(t)]$$

The left-hand side of (17) is obviously the marginal product of the stock of reserves. We now show that the right-hand side of (17) is the ratio of the marginal after-tax net cost of holding reserves to the marginal after-tax net return from producing reserves. Consider first the numerator. From (13), we see that $\eta(t)$ is the marginal after-tax cost of a unit of proved reserves;[8] therefore $[1/\eta(t)][d\eta(t)/dt]$ is the own-rate of interest on reserves. Since $i(t)$ is the after-tax monetary rate of interest, the numerator of the right-hand side of (17) is the marginal after-tax net cost of holding a unit of reserves. Next consider the denominator. The first term $\{1-y(t)-u(t)\ [1-y(t)-z(t)]\}\pi(t)p(t)$ is the marginal after-tax revenue from selling a unit of output. The second term $\eta(t)$ is the marginal after-tax cost of a unit of reserves to replace that which is produced. The difference between the two terms is the marginal after-tax net return from producing a unit of reserves.

[8] Let $\beta=[(1-u)(q_1+q_2)+(1-uD)q_3]+[(1-u)(\partial q_1/\partial I+\partial q_2/\partial I)+(1-uD)\partial q_3/\partial I]I$ in equation (13). Note that $\beta$ is the marginal change in the time t value of after-tax cash flow with respect to investment expenditure. From (13), $\eta=\beta(\partial\phi/\partial I)^{-1}$. Since $\partial\phi/\partial I$ is the marginal increase in reserves from investment expenditure, $(\partial\phi/\partial I)^{-1}$ is the marginal *before-tax* cost of reserves; hence $\beta(\partial\phi/\partial I)^{-1}$ is the marginal *after-tax* cost of reserves at time t.

The right-hand side of (17) is the inverse of the output-input, after-tax relative price variable $h$, which is shown below to be an argument of the investment functions:

$$(18)\quad h(t) = [\{1-y(t)-u(t)[1-y(t)-z(t)]\}\pi(t)p(t)-\eta(t)] \div \left[\left\{i(t) - \frac{1}{\eta(t)}\frac{d\eta(t)}{dt}\right\}\eta(t)\right]$$

We assume a *CES* production function,

$$(19)\quad Q(t) = Ae^{\gamma t}\{a\Omega(t)^{-v} + (1-a)L(t)^{-v}\}^{-b/v}$$

where $A>0$ is the scale parameter; $\gamma\geqq 0$ is the rate of technological change; $a\in(0,1)$ is the input-intensity parameter; $(1+v)^{-1}\in(0,1]$ is the elasticity of factor substitution, restricted so that both inputs are necessary for positive production; and $b\in(0,1]$ is the degree of homogeneity, restricted so that the production function is concave. Equations (7) and (19) imply that the marginal product of reserves is

$$(20)\quad \frac{\partial Q(t)}{\partial R(t)} = \frac{\partial Q(t)}{\partial\Omega(t)}\frac{\partial\Omega(t)}{\partial R(t)} = abA^{-v/b}[e^{\gamma t}]^{-v/b}[Q(t)]^{(1+v/b)}[R(t)]^{-(1+v)}[S(t)]^{-\theta v}$$

From equations (17), (18), and (20), we obtain the following expression for the optimal stock of proved reserves:

$$(21)\quad R(t) = [abA^{-v/b}]^{1/(1+v)}\cdot[h(t)]^{1/(1+v)}[Q(t)]^{(b+v)/b(1+v)}\cdot[S(t)]^{-\theta v/(1+v)}[e^{\gamma t}]^{-v/b(1+v)}$$

Taking a logarithmic transformation of (21) yields the optimal reserves stock equation

$$(22)\quad ln\,R(t) = \alpha_0 + \alpha_1\,ln\,h(t) + \alpha_2\,ln\,Q(t) + \alpha_3\,ln\,S(t) + \alpha_4 t$$

where:

$$(23) \quad \alpha_0 = \frac{1}{1+v}[ln\ a + ln\ b] - \frac{v}{b(1+v)} ln\ A$$

$$\alpha_1 = \frac{1}{1+v}$$

$$\alpha_2 = \frac{b+v}{b(1+v)}$$

$$\alpha_3 = -\frac{\theta v}{1+v}$$

$$\alpha_4 = -\frac{\gamma v}{b(1+v)}$$

Replacing continuous time by discrete time in (22), and adding the error term $\epsilon_t$, we get the reserves stock estimating equation

$$(24) \quad ln\ R_t = \alpha_0 + \alpha_1\ ln\ h_t + \alpha_2\ ln\ Q_t + \alpha_3\ ln\ S_t + \alpha_4 t + \epsilon_t$$

Differentiation of (22) yields the proportional net investment equation

$$(25) \quad \frac{dR(t)/dt}{R(t)} = \alpha_4 + \alpha_1 \frac{dh(t)/dt}{h(t)} + \alpha_2 \frac{dQ(t)/dt}{Q(t)} + \alpha_3 \frac{dS(t)/dt}{S(t)}$$

Replacing continuous time by discrete time in (25), and adding the error term $\epsilon_t'$, we get the proportional net investment estimating equation

$$(26) \quad \frac{\Delta R_t}{R_t} = \alpha_4 + \alpha_1 \frac{\Delta h_t}{h_t} + \alpha_2 \frac{\Delta Q_t}{Q_t} + \alpha_3 \frac{\Delta S_t}{S_t} + \epsilon_t'$$

The net investment estimating equation with error term $\epsilon_t''$ is

$$(27) \quad \Delta\ ln\ R_t = \alpha_4 + \alpha_1 \Delta ln\ h_t + \alpha_2 \Delta\ ln\ Q_t + \alpha_3 \Delta\ ln\ S_t + \epsilon_t''$$

Equation (27) can be derived either by taking a first-order Taylor series approximation of (22), or by taking first differences in (24).

## II. Data Sources

In this section, we discuss the selection and use of empirical measures of the cost of acquiring proved reserves and of the output and price of crude petroleum. We also briefly describe the other data used in the estimations.

### A. *Cost of Acquiring Petroleum Reserves*

The only suitable data on reserve acquisition costs which are broken down by state are those published by the Joint Association Survey (*JAS*) for "costs of drilling and equipping wells" (hereafter *D&E* costs). These data are available separately for successful oil wells, successful gas wells, and total dry holes; they appear to cover the vast bulk of "proving up" outlays. The *JAS* series on *D&E* costs is only available continuously for the years 1959–71, restricting the empirical estimations to thirteen observations.[9]

### B. *Current Petroleum Output and Price*

For the output variable $Q$, U.S. Bureau

[9] American Petroleum Institute (*API*) et al., Section I. The *D&E* costs include only the "Christmas tree" on wells to be used in production. The procedures underlying the *JAS* data have been criticized by Franklin Fisher; we have not evaluated the data published since Fisher wrote (i.e., those for 1961–71), but the methodology appears to have been substantially improved (see, e.g., Morris Adelman, p. 121). *JAS* published *D&E* costs for 1953, 1955, and 1956, but not for 1954 or 1957 and 1958; the early data are of much lower quality than those for 1959–71. The Chase Manhattan Bank (*CMB*) and the *JAS* (*API* et al., Section II) publish series on exploration and development outlays but only for the entire United States. The *CMB* series would not be suitable for econometric work because it is intended as information for investors, not as a consistently defined time-series. Moreover, it includes production facilities beyond the "Christmas tree."

of Mines (*USBM*) data were used in constructing a Divisia quantity index[10] of current outputs of oil, natural gas (nonassociated and associated-dissolved), and natural gas liquids—i.e., all petroleum production from which revenue was received.[11] The *USBM* natural gas figure used in the output Divisia index was "marketed output," which is equal to "gross" output from oil and gas wells, less "repressuring" and "losses."

For the price variable $p$, a Divisia price index of oil, natural gas, and natural gas liquids was constructed. For oil and natural gas liquids, *USBM* data on values realized "at the well" (oil) and "at plants" (natural gas liquids), divided by the appropriate *USBM* output figure, were used. For natural gas, the relevant price for decisions on new reserves in year t is the price obtained on new contracts made in that year, not average realized prices which include sales under long-term contracts made in years past; accordingly, a series for "new contract" prices prepared by Foster Associates for the Energy Policy Project was used.

### C. *Other Data Sources*

1) The stock of proved reserves $R$. Annual data on end-of-year proved reserves of oil and natural gas, in American Petroleum Institute, American Gas Association, and Canadian Petroleum Association, were used in a Divisia index of reserves.

2) Market-demand factor $S$. The values of this variable were those set by the *TRRC;* the annual market-demand factor was calculated as a percentage equal to the average of the twelve monthly figures.

3) *U.S.* corporate income tax rate $u$. Data for 1959–69 were obtained from Joseph Pechman, p. 118; the rates for 1970 and 1971 were taken from the U.S. Internal Revenue Code.

4) Percentage depletion rate $z$. The statutory percentage depletion rate was used for want of a time-series of the effective rate; the latter rate would be less than the former because of the net income limitation.

5) Average production and severance tax rate $y$. This rate was calculated from data in *API* et al., Section II, on state and local taxes paid on oil and gas production, divided by the total value of petroleum production.

6) Discounted value at time t of $1 of depreciable cost incurred at time t, $D$. Iterations from 0.4 to 0.8 in increments of 0.1 showed very little variation in the results. We used the conservatively high value of $D=0.8$, which is the approximate value of $1 of depreciable cost over five years at 12 percent by the sum-of-years-digits depreciation method (see Hall and Jorgenson).

7) Interest rate $i$. Two alternative time-series for the after-tax rate of interest were used. (a) The quantity $(1-u)$ times Moody's index of all "industrial" bond yields, for thirty-six bonds, referred to as the "debt" interest rate. (b) The quantity $(1-u)$ times the inverse of Standard and Poor's composite "price-earnings ratio," referred to as the "equity" interest rate.

8) Royalty share $(1-\pi)$. Based on information in McDonald (1971, p. 14, and 1963, p. 103, n. 132), we iterated over values from 0.10 to 0.20. Since the empirical results varied little between iterations, we follow *API* et al., Section II, and report the results for a royalty share of 15 percent.

## III. Empirical Estimations

In this section, we first discuss the construction of the relative price variable $h$ from the data discussed in Section II. We

[10] On Divisia quantity and price indexes, see Herman Wold and Lars Juréen, and Jorgenson and Griliches.

[11] The *USBM* data are given in convenient form through 1969 in *API*. For 1970 and 1971, the *USBM*'s *Mineral Industry Surveys* were used.

then report ordinary least squares estimates of the reserves investment equations derived in Section I.

The first step in constructing the time-series of $h$ was to calculate an average-cost proxy for the marginal after-tax cost of reserves $\eta$ defined by (13). To separate $D\&E$ costs on successful wells into intangible (expensible) and tangible (depreciable) components, we regressed intangibles on total $D\&E$ costs for successful oil wells and for successful gas wells, using *JAS* data for 1959–64. The total figure for each type of well was then multiplied by the fitted slope coefficient and by one minus the coefficient to obtain intangible and tangible costs, respectively.[12]

The time-series of average costs of acquiring reserves by type of tax treatment were then obtained by dividing dry-hole, intangible, and tangible $D\&E$ costs by gross additions to petroleum reserves. Let $\Lambda_t$ be a Divisia quantity index of $(R_t - R_{t-1} + Q_t)$ for crude oil and nonassociated natural gas in year t. Also let $X_{dt}$, $X_{ct}$, and $X_{gt}$ be $D\&E$ costs in year t on dry holes, successful crude oil wells, and successful gas wells, respectively. Finally, let $\beta_c$ and $\beta_g$ be the estimated proportions of intangibles in $D\&E$ costs in year t for successful oil wells and successful gas wells, respectively. Then for year t the average dry-hole cost of new reserves was calculated as $X_{dt}/\Lambda_t$; the average intangible cost of new reserves was $(\beta_c X_{ct} + \beta_g X_{gt})/\Lambda_t$; and the average tangible cost of new reserves was $[(1-\beta_c)X_{ct} + (1-\beta_g)X_{gt}]/\Lambda_t$.

The last step in calculating the average-cost proxy for the time-series of $\eta$ was to multiply the above dry-hole and intangible costs by $(1-u)$ and to multiply the above tangible costs by $(1-uD)$. The time-series of $\eta$ in turn was combined with the production-tax rate $y$, the percentage depletion rate $z$, the royalty share $\pi$, the price index of petroleum production $p$, and the rate of interest $i$, to calculate the time-series of the output-input, after-tax relative price variable $h$, given by (18). There is no time trend in the time-series of $\eta$; the ratio of the variance to the mean of the series is less than 0.2 percent. This allowed us to assume that over the time period covered by our data, the own-rate of interest on proved reserves was zero. Consequently, the term $[1/\eta(t)][d\eta(t)/dt]$ was set equal to zero in calculating the time-series of $h$.

Market price $p$ is a component of $h$, and the quantity of output $Q$ enters the estimating equations as another explanatory variable. During the period covered by our data, authorities in the five prorationing states effectively controlled the price of crude oil through the policy of *MDP* (under the protective cover of the import quota). By varying the market-demand factor, the state authorities in effect selected price-quantity pairs from the domestic demand curve. It is therefore appropriate in the following regressions to assume that market price and output were both exogenously determined variables over the period studied.[13]

The results of least squares regressions for the estimating equations derived in Section I, using the data described in Section II and the procedures detailed above, are reported in Table 1 (debt interest rate) and Table 2 (equity interest rate). Given the small number of degrees of freedom, the results of the least-squares regressions are encouraging. All estimated coefficients of explanatory variables are highly

[12] The *JAS* definitions of intangibles and tangibles correspond closely to those in the federal tax law (e.g., *API* et al., 1964, section I, pp. 7–8). Scatter diagrams of intangibles against total $D\&E$ costs for successful wells indicated very tight linear fits for both oil and gas wells. Least squares regressions gave $\bar{R}^2 > 0.999$; the constant terms were not significant.

[13] For further explanation of this point, see fn. 17 and the accompanying discussion in Section IV below.

TABLE 1—REGRESSION RESULTS: DEBT INTEREST RATE

| | Coefficients | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | $h_t$ | $Q_t$ | $S_t$ | $t$ | $\bar{R}^2$ | $DW$ | $F$ |
| | $\alpha_0$ | $\alpha_1$ | $\alpha_2$ | $\alpha_3$ | $\alpha_4$ | | | |

*Note:* See Table 1 for explanation of terms.

significant; moreover, they are quite stable between the stock and the flow estimating equations. The $\bar{R}^2$ are relatively high; indeed, we expected worse fits for the first-difference equations, (26) and (27). The Durbin-Watson statistics evidence virtually no serial correlation of the residuals for the debt interest rate and only a weak tendency towards negative serial correlation with the equity interest rate.[14] The $F$-statistics for all six equations estimated exceed the confidence values at the 1 percent level of significance.

The signs of the estimated coefficients reported in Tables 1 and 2 can be interpreted as follows. For the stock equation (24), producers held a larger stock of proved reserves during the period studied, *ceteris paribus*, (a) the higher was the output-input relative price variable ($\alpha_1>0$); (b) the higher was the rate of current petroleum output ($\alpha_2>0$); (c) the smaller was the market-demand factor ($\alpha_3<0$);[15]

[14] Our colleague, Ronald Ehrenberg, has pointed out that regardless of the calculated values of the Durbin-Watson statistics for the equations estimated, the apparent absence of serially correlated residuals can be true for only the stock equation or the flow equations but not for both simultaneously.

[15] One might be tempted to think that a more stringent (smaller) value of the market-demand factor would have *reduced* the stock of reserves by raising the price of the effective flow of reserve services into the production of crude petroleum (e.g., Adelman, p. 106). In fact, producers were forced by the policy of *MDP* to increase the reserve/output ratio for any given level of output. Hence the negative relationship which we find is the one to be expected.

TABLE 3—IMPLIED PARAMETER VALUES: DEBT INTEREST RATE

| Equations | Parameters $1/(1+v)$ | $b$ | $\theta$ | $\gamma$ |

and (d) the lower was the rate of technological change ($\alpha_4<0$). For analogous interpretations of the two flow equations (26) and (27), add a modifying phrase, "proportional change in" or "change in," where appropriate in the above interpretation of the stock equation.

We report in Tables 3 and 4 the values of the production function parameters $1/(1+v)$, $b$, $\theta$, and $\gamma$ which from (23) are implied by the estimated coefficients reported in Tables 1 and 2. The estimates of $1/(1+v)$, which is the elasticity of substitution between reserves and nonreserve inputs and is equal to the coefficient $\alpha_1$, are contained in $(0, 1]$ as required by our specification of the production function. In addition, the values of the elasticity of substitution are quite small, plausibly suggesting that it is difficult to substitute nonreserve inputs for proved reserves in producing crude petroleum. The estimates of $b$, $\theta$, and $\gamma$ are biased because they are non-linear functions of the $\alpha_j$. The estimates of $b$, which is the homogeneity parameter and is equal to $(\alpha_1-1)/(\alpha_1-\alpha_2)$, are not contained in $(0, 1]$ as required by our specification of the production function. The estimates of $\theta$, which is the elasticity of the full-time equivalent stock of reserves with respect to the market-demand factor and is equal to $\alpha_3/(\alpha_1-1)$, are positive as required by (7); they are also much smaller than unity, suggesting that crude petroleum producers in the prorationing sector did indeed respond to *MDP* by utilizing their proved reserves more intensively than they would have under literal "shutdown days" prorationing. Finally, the estimates of $\gamma$, which can be interpreted as the rate of technological change and is equal to $\alpha_4/(\alpha_1-\alpha_2)$, are nonnegative as required by our specification of the production function; furthermore, the implied values of 3.3 to 3.6 percent per annum are reasonable.

## IV. Conclusions and Policy Implications

Our empirical estimates of the determinants of investment in crude petroleum reserves in the prorationing sector of the *U.S.* petroleum industry for 1959–71 are consistent with the model of investment in crude petroleum reserves presented in Section I. The results indicate that several public policies have significantly affected investment in reserves in the prorationing sector. Three of the four explanatory variables depend on instruments of government control. The relative price variable is a function of the special federal corporation income tax provisions for petroleum. The market-demand factor is under the direct control of state prorationing authorities. In addition, both those authorities and the federal government exercised control over crude oil price and quantity during the period studied, through the policies of *MDP* and the oil import quota, respectively.

Two of the three policies had direct par-

tial effects on investment in petroleum reserves which can be inferred from our estimates. In addition, all three policies had indirect partial effects through induced changes in equilibrium price and quantity, which can also be inferred from our estimates. The total effects can be determined from our results if both the direct and the indirect effects have the same sign; otherwise, further information is required. We consider first the direct and then the indirect policy effects on petroleum reserves.

The special federal tax provisions for petroleum corporation income increase the value of the relative price variable $h$, given the price of petroleum output.[16] Thus the significantly positive estimates of $\alpha_1$ imply that those provisions increased investment in reserves compared to uniform tax treatment. Similarly, the significant positive estimates of $\alpha_3$ imply that setting the market-demand factor $S$ at less than unity increased investment in reserves compared to the absence of effective *MDP* ($S=1$).

The oil import quota indirectly affected investment in prorationing-sector petroleum reserves by restricting the quantity of imports. Given the market-demand factor and the special tax provisions, reduced imports would lead to a higher price in the *U.S.* market; the higher price in turn would induce an increase in quantity supplied in the prorationing sector. Therefore, the significantly positive estimates of $\alpha_1$ and $\alpha_2$, the coefficients on relative price and output, imply that the oil import quota increased investment in petroleum reserves.

The indirect effects on petroleum reserves of the special tax provisions and *MDP* involve shifts in the petroleum supply curve. It can be shown that the model developed in Section I leads to a prorationing-sector supply function relating quantity supplied to the market-demand factor, time, and two output-input relative price variables, our $h$ and another relative price, which we have not explicitly defined, for the nonreserve input. In order to represent the supply function as a family of supply curves in price-quantity space, we define the following variable:

$$(28) \quad c(t)=\frac{i(t)\eta(t)}{\pi(t)\{1-y(t)-u(t)[1-y(t)-z(t)]\}}$$

Given the assumption of a zero own-rate of interest on reserves (see Section III), statements (18) and (28) imply

$$(29) \qquad h(t)=\frac{p(t)}{c(t)}-\frac{1}{i(t)}$$

Then holding constant the price of the nonreserve input and the rate of interest, quantity supplied in the prorationing sector at time t is an increasing function of $p$ and $S$ and a decreasing function of $c$. A similar argument leads to a supply function for the nonprorationing sector which is increasing in $p$ and decreasing in $c$; the market-demand factor $S$ does not, of course, appear in the nonprorationing-sector supply function. Since total domestic supply is the sum of the quantities supplied by the two sectors, the total supply function can be represented by the family of supply curves $Q(\cdot)$ in the price-quantity space of Figure 1.

Let $D(p)$ in Figure 1 be the demand curve for petroleum in the domestic market. Then suppose that the special tax provisions were made more generous, so that $c$ decreased from (say) $c''$ to $c'$; as a result, the supply curve would shift from $Q(p, c'', S')$ to $Q(p, c', S')$. Given $D(p)$, the shift in supply would in turn reduce equilibrium price from $p^b$ to $p^a$ and increase the

[16] From (18), $h$ is seen to be an increasing function of the rate of percentage depletion $z$. It can be seen from (13) that the expensing of intangible drilling costs transfers marginal acquisition costs in the amount $[q_2+I(\partial q_2/\partial I)]$ from a term with weight $[1-uD]$ to a term with the smaller weight $[1-u]$.

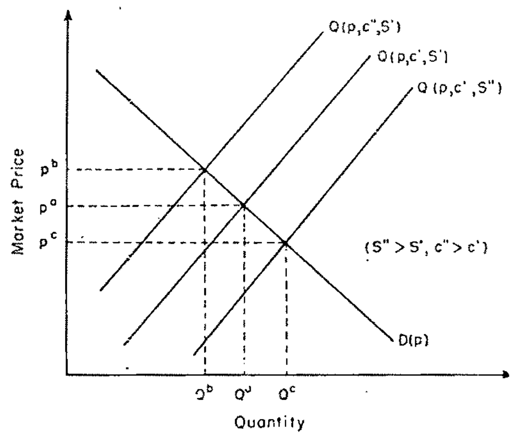

FIGURE 1

quantity supplied from $Q^b$ to $Q^a$. Part of the increase in quantity supplied would come from the prorationing sector. Thus making the special tax provisions more generous would (*ceteris paribus*) reduce market price and increase the quantity supplied (and vice versa for making the provisions less generous).

To isolate the indirect effects of varying the special tax provisions, we take the differential of (22), set $dS_t$ and $dt$ equal to zero, and use (29) to obtain

$$(30) \quad dR_t = -\frac{\alpha_1 p_t R_t}{(c_t)^2 h_t} dc_t + \frac{\alpha_2 R_t}{p_t}\left[\frac{\alpha_1 p_t}{\alpha_2 c_t h_t} - E_t\right] dp_t$$

where $E_t$ is the price elasticity of demand for petroleum at time t. The first term on the right-hand side of (30) is the direct effect on reserves of changes in the special tax provisions; since $dc_t$ is negative, the sign of this term is positive, which is consistent with our earlier finding that the direct effect of the special tax provisions was to increase reserves.

The second expression on the right-hand side of (30) is the indirect effect on reserves of changing the special tax provisions. As noted above in discussing Figure 1, making those provisions more generous reduces the market price. Therefore $dp_t$ is negative and, since $\alpha_2$ is positive, the sign of the indirect effect is the opposite of the sign of the term in brackets. The latter sign is analytically indeterminate, depending on whether $\alpha_1 p_t/\alpha_2 c_t h_t$ is greater or less than $E_t$. To place limits on the sign of the bracketed term, we calculated the values of $\alpha_1 p_t/\alpha_2 c_t h_t$, using the estimates of $\alpha_1$ and $\alpha_2$ (see Tables 1 and 2) plus the observed figures for $p_t$, $h_t$, and $c_t$ for 1959–71; these values vary from 0.0366 to 0.0659. Therefore the bracketed expression in (30) was negative in each year between 1959 and 1971 in which the price elasticity of demand for crude petroleum exceeded 0.0659. If the bracketed expression was negative, the indirect effect as a whole would have been positive, thereby reinforcing the direct effect. On the assumption that $E_t$ was larger throughout the period than the very low value of 0.0659, we tentatively conclude that both the direct and the indirect effects of the special tax provisions increased the stock of proved reserves of petroleum.

To examine the indirect effect of market-demand prorationing on reserves, let us begin with the supply curve $Q(p, c', S'')$ in Figure 1. Now suppose *MDP* is made more stringent by a reduction in the market-demand factor from $S''$ to $S'$. We showed above that this reduction would directly increase the stock of petroleum reserves. There would also be an indirect effect, however, since moving from $S''$ to $S'$ would shift the supply curve in Figure 1 from $Q(p, c', S'')$ to $Q(p, c', S')$.[17] As a result, equilibrium price would increase from $p^c$ to $p^a$ and total quantity supplied would decrease from $Q^c$ to $Q^a$. By reasoning

[17] The ability to shift the supply curve in market price-output space is the reason why effective *MDP* enables the prorationing boards to pick points on the demand curve. Thus, so long as prorationing is effective, market price and output are exogenous to the prorationing sector producer.

analogous to that above for the special tax provisions, the indirect effect of *MDP* would be a decrease in reserves, provided that the price elasticity of demand for crude petroleum was greater than 0.0659. Because the direct and indirect effects have opposite signs in this case, the direction of the total effect of *MDP* on petroleum reserves cannot be determined from our estimates alone. Additional information on the supply and demand functions is required to determine the net total effect.

The Arab embargo of October 1973 has prompted interest in the question of national "independence" in oil. Independence can be defined as having the capacity for self-sufficiency—that is, the capability of being independent of foreign suppliers if the need arises. It can be promoted through actual self-sufficiency in production or through holding excess domestic capacity which can be used in the event that foreign supplies are disrupted. For a depletable resource such as petroleum, increasing domestic output in order to pursue self-sufficiency in production in one period will make it more expensive to be self-sufficient or to hold excess capacity in later periods. In contrast, a policy which promotes independence by inducing domestic producers to hold excess capacity need not mortgage future independence by increasing the present rate of depletion of the resource.[18]

An interesting question is whether past public policies have contributed to or detracted from national independence in oil. Proponents of those policies have claimed that they promoted a "strong petroleum industry" and thus increased "national security." Our empirical estimates permit us to shed some light on this question. In what follows, we analyze the effects of past policies on self-sufficiency as measured by the quantity of imports; discussion of policy effects on alternative measures of self-sufficiency is relegated to footnotes. We also analyze the effects of past policies on independence as measured by the ratio of imports to domestic proved reserves; because reserves are a measure of productive capacity, this ratio is one index of the capability of the domestic petroleum industry to replace imports.

We saw above that, *ceteris paribus*,[19] the indirect effects of the special petroleum tax provisions were transmitted in part through an increase in domestic quantity supplied. Given that the oil import quota was administered by limiting imports to a fixed percentage of domestic production,[20] the increase in domestic production led to an increase in the quantity of imports. Thus the special tax provisions tended to reduce self-sufficiency in oil during the period 1959–71.[21] In addition, the increased domestic production caused the faster depletion of domestic petroleum resources; hence the existence of the special tax provisions in the past has made the present pursuit of independence more costly. Finally, we saw above that the total effect of the special tax provisions was probably to increase investment in proved reserves. Since those provisions also increased imports, we cannot determine their net effect on past independence in oil as

[18] These points are fully explained in the authors' paper, 1975b.

[19] All changes and effects discussed below are partial ones.

[20] James Burrows and Thomas Domencich, p. 12; Cabinet Task Force, p. 10. There was a gradual accumulation of exceptions to this policy criterion but they are irrelevant to an analysis of partial effects.

[21] Other measures of self-sufficiency are the ratio of imports to domestic production $Q_m/Q_d$, and the ratio of imports to total domestic quantity demanded $Q_m/D$. Given the way the import quota was administered, the first measure $Q_m/Q_d$ could not be changed by any other petroleum policy. Because the special tax provisions increased both $Q_m$ and $D$, the second measure $Q_m/D$ would have varied with tax policy; unfortunately, our estimates do not enable us to calculate the relative magnitudes of the two increases. Note that a different administration of the oil import quota would have led to other conclusions about tax policy effects on the several measures of self-sufficiency and independence.

measured by the ratio of imports to proved reserves.

As we showed above, the policy of market-demand prorationing (*MDP*) reduced domestic petroleum production. Given the way the import quota was enforced, *MDP* therefore reduced oil imports and thereby increased past energy self-sufficiency.[22] Because the direct effect of *MDP* on reserves was positive but the indirect effect was negative between 1959 and 1971, we cannot determine the net effect of *MDP* on past independence in oil as measured by the ratio of imports to reserves. We can say, however, that past *MDP* made the present pursuit of independence less costly because the lower rate of petroleum production reduced the rate of depletion of domestic petroleum resources.[23]

The oil import quota, of course, reduced the quantity of imports compared to a policy of free trade in oil; thus it increased past self-sufficiency in oil.[24] In addition, we found that the quota indirectly increased investment in proved reserves by raising the market price of petroleum. The combination of lower imports and greater reserves means that the quota increased past independence in oil as measured by the ratio of imports to reserves. The increased market price, however, led to larger domestic production and hence faster depletion of domestic petroleum resources. The oil import quota of the past therefore made the pursuit of present independence more expensive.

A lesson in the importance of evaluating related public policies simultaneously rather than in isolation from one another is provided by the interaction between the import quota and the special petroleum tax provisions. The quota was ostensibly intended to promote self-sufficiency in oil. We saw above, however, that the special tax provisions in the presence of the quota tended to reduce self-sufficiency in oil during the period 1959–71 by increasing the quantity of imports. Ironically, had there been no import quota, the special tax provisions would have *reduced* oil imports,[25] thereby increasing self-sufficiency. Furthermore, without the quota the special tax provisions would have increased past independence in oil, in that the increase in reserves coupled with the reduction in imports would have decreased the import-reserve ratio. With the quota, in contrast, both the numerator and the denominator of the ratio were increased, leaving the effect on independence indeterminate.

In conclusion, we wish to stress two implications of the preceding discussion of independence in oil. First, in evaluating a particular petroleum policy, one must take into account possible interactions with other policies; we found, for example, that the effects of the special tax provisions on self-sufficiency would have been reversed, had the oil import quota not existed. Second, our analysis reveals that past policies, contrary to assertions by their proponents, did not unambiguously promote national

[22] Using the alternative measure $Q_m/D$, the effect of prorationing on self-sufficiency is qualitatively indeterminate, since both components of the ratio would be reduced.

[23] We abstract here from the considerable inefficiencies, due largely to overdrilling and favoritism towards "stripper" wells, introduced by *MDP* when it was an effective policy; see Adelman.

[24] The quota unambiguously increased self-sufficiency according to the alternative measure $Q_m/Q_d$, since the numerator was reduced and the denominator was increased. According to the measure $Q_m/D$, however, the effect is ambiguous, since both components were reduced (domestic quantity demanded was reduced by the higher market price caused by the quota).

[25] If the supply curve of imports was horizontal and (in the absence of an import quota) constituted the controlling marginal supply price in the domestic market, the increase in domestic supply resulting from more generous federal tax treatment would mean larger domestic production and hence fewer imports, since the total quantity demanded would not change. For an upward-sloping import supply curve, the increase in domestic supply would reduce the market price and hence also reduce the quantity of imports supplied in the market.

independence in oil. In designing future petroleum policies, then, attention should be paid to achieving consistency among different policies. Moreover, public officials would do well to explore alternative sets of policies which may dominate the past set in the sense of offering (say) a lower-cost time path for national independence in oil (see, for example, the authors, 1975b).

# Do Income Taxes Reduce the Effectiveness of Monetary Policy?

*By* Stanley W. Black and Rudolph C. Blitz*

The contemporary lore of monetary and fiscal policy contains two general propositions asserting that high income taxes reduce the effectiveness of monetary policy. One is a reduction in the interest sensitivity of investment demand, and the second is a fall in the value of the multiplier. For example, Warren Smith's recent textbook *Macroeconomics* describes the first effect:

> . . . there are a priori reasons for doubting that investment decisions would be likely to be strongly affected by changes in borrowing costs. One is that interest is deductible as an expense in calculating income for tax purposes. With a corporate income tax rate of 50 percent, an increase in the interest rate by one percentage point, from 5 to 6 percent, would mean an increase of only half a percentage point, from 2.5 to 3 percent, in the *effective* interest rate after adjustment for tax deductibility. Thus, the deductibility of interest under the income tax probably serves to blunt rather substantially the effects of interest rate changes on investment. [p. 204]

It is also generally known that income taxes reduce the value of the multiplier, since the taxes are a leakage from the income stream. Therefore, a reduction in the tax rates on personal and corporate income would be expected to have a two-fold effect in strengthening the impact of monetary policy. First, the interest sensitivity of investment spending would be increased so that a fall in the interest rate would have a larger impact on investment demand. Second, the multiplier would be larger at a lower tax rate so that the larger increment in investment demand would have a magnified effect on aggregate income. Here we assume that the personal and corporate tax rates are changed together in an across-the-board fashion.

In the course of investigating these two propositions rather carefully, we have discovered that the first one is incorrect for business investment, at least in the context of two well-known theories of investment behavior and the present tax structure of the United States. This was earlier pointed out by Paul Samuelson in a brief remark which did not examine the full implications of tax rates for investment. In fact, no general statement about the effects of tax rates on the interest sensitivity of investment can be made without considering the prevailing mix of debt and equity (in turn, influenced by the tax system) and the relative flows of investment to sectors subject to different tax rules (the business and household sectors). This paper is devoted to the exposition of these findings. To begin with, we discuss the effects of tax rates on the cost of capital as defined in the SSRC-MIT-PENN quarterly econometric model of the *U.S.* economy (the *SMP* model) and the underlying Jorgenson and Modigliani-Miller theories of investment behavior. In this context, we demonstrate how the tax structure combined with the *SMP* specification of cost of capital invalidates the first proposition on the sensitivity of investment to the after-tax rate of interest. Next, we illustrate our findings in a simple *IS-LM* framework, showing how changes in tax rates in turn change the effectiveness of monetary policy, both through the interest sensitivity of investment and through the multiplier.

## I. The Effect of Tax Rates on the Interest Sensitivity of Investment

At the most elementary level, the cost of capital for a firm is the opportunity cost of the debt or equity funds which must be attracted to permit the acquisition of physi-

* Vanderbilt University.

cal assets. The rental price of a capital good can be expressed as the quasi rent $Q$ which must be earned by the marginal capital good to justify its purchase, given the price of the capital good $P$, the marginal cost of capital as a percentage rate $R$, and the tax structure and other costs. Ignoring taxes and depreciation for a moment, the marginal investment must satisfy $Q/P=R$. A general formula for the rental price based on Robert Hall and Dale Jorgenson's theory of investment behavior has been developed by Frank de Leeuw and Edward Gramlich to describe the investment functions of the *SMP* model.

Let $D$ be the physical rate of depreciation, $TP$ be the property tax rate, and $G$ the expected rate of capital gains. Denote the income tax rate by $t$, the rate of investment tax credit by $u$ (treated as a reduction in the cost of purchasing the capital good). Let $v$ and $z$ be the proportions of the rental $Q$ and the capital gain $G$ that are taxable, while $w$, $x$, and $y$ are the proportions of depreciation $D$, cost of capital $R$, and property tax $TP$ that are deductible from taxable income. Then the marginal investment must earn a quasi rent given by the following formula:

$$\text{(1)} \quad \frac{Q(1-vt)}{P(1-u)} = D(1-wt) + R(1-xt) + TP(1-yt) - G(1-zt)$$

Under stationary assumptions and perfect certainty, this formula can be derived very easily.[1]

To draw out the implications of equation (1) for our problem, let us ignore depreciation, property taxes, expected capital gains, and the investment tax credit. Then one has

$$\text{(2)} \quad \frac{Q}{P} = R\frac{(1-xt)}{(1-vt)}$$

$$\text{(3)} \quad \frac{\partial Q/P}{\partial R} = \frac{1-xt}{1-vt}$$

Now for fully mortgaged owner-occupied residential housing or other credit-financed consumer durables, the rental is nontaxable ($v=0$), but the interest is deductible ($x=1$). The result is $Q/P=R(1-t)$, and a reduction in the tax rate raises the derivative of the rental rate with respect to the cost of capital (since $\delta(Q/P)/\delta R=1-t$ in this case). This is entirely consistent with the first proposition discussed above.

In the case of business investment, however, all income is taxable ($v=1$) while only a part of the cost of capital, that relating to debt-financed investment, is deductible, so that $x$ is substantially less than one. In the case of all-equity finance, $x=0$. For the *SMP* model, Charles Bischoff took $x=.2$ based on the ratio of debt to equity in the corporate sector. (This assumes that the debt-equity ratio is a constant which may not be true when there is a change in the tax rate. We return to this point in fn. 3.) Therefore we obtain

$$\text{(4)} \quad Q/P = \frac{R(1-.2t)}{1-t}$$

and a cut in the tax rate *lowers* the derivative of the rental rate with respect to the cost of capital! Allowing for depreciation and the investment tax credit makes no difference to this result, which is based directly on the application of Jorgenson's theory of investment behavior. As a matter of fact, exactly the same result as given in (4) can be obtained from Modigliani and Miller's theory of investment behavior under uncertainty.[2]

As should be apparent by now, the actual effect of a change in tax rates on the interest

[1] Ignoring income taxes to begin with, and letting $D'=D\cdot P$, $TP'=TP\cdot P$, $G'=G\cdot P$ denote the *amounts* of depreciation, property taxes, and expected capital gains, one has the condition for profitability of the investment as:

$$P = \sum_{i=1}^{\infty} \frac{Q-D'-TP'+G'}{(1+R)^i} = \frac{Q-D'-TP'+G'}{R}$$

Then

$$R = \frac{Q}{P} - \frac{D'}{P} - \frac{TP'}{P} + \frac{G'}{P} = \frac{Q}{P} - D - TP + G$$

or

$$\frac{Q}{P} = R + D + TP - G$$

Allowing for taxes, one must define each of these factors *after tax*, leading to equation (1).

[2] According to Modigliani and Miller, the cost of capital for a firm is "the minimum prospective yield an investment project must offer to be just worth undertaking from the standpoint of the present stockholders" (1963, p. 439). In their notation, $\overline{X}$ is the

sensitivity of investment will depend crucially on the taxable proportion of the quasi rent of capital $v$ relative to the deductible proportion of the cost of capital $x$, as defined by the tax laws. In the above cases we had $v<x$ or $v>x$. But if $v=x$, the formula again becomes $Q/P=R$, and the tax rate has no effect. Sample situations with $v=x$ include either business investment completely financed by debt ($v=x=1$); or equity-financed outlays for research and development, mineral exploration costs charged to current expense, and advertising outlays to enhance goodwill ($v=x=0$). Richard Musgrave, p. 343, shows that $v=0$ for investment outlays charged to current expense.

The use of equation (3) to analyze the effectiveness of monetary policy depends on the assumption that the after-tax cost of capital, at which the future earnings of investment projects are discounted, is a variable influenced by current market yields. As Bischoff notes, "... the appropriate empirical measure of the discount rate is subject to a great deal of disagreement, but from the point of view of policy the choice is crucial" (p. 83). Hall and Jorgenson, for example, assume that the discount rate or cost of capital is a constant, while Modigliani and Miller (1958) try to show that it is influenced by market interest rates.

## II. An *IS-LM* Framework

For the purpose of illustrating our results on changes in the interest sensitivity of investment caused by changes in the tax rate and integrating them in turn with the effect of tax changes on the value of the multiplier, we shall use a simple linear *IS-LM* framework.

Defining all variables in real terms, let consumption $C$ be a linear function of disposable income $Yd$:

$$C = aY_d + b \tag{5}$$

Assuming a proportional tax rate $t$ and no business saving, disposable income $Y_d$ is a linear function equal to national product $Y$ minus taxes $T$:

$$Y_d = (1-t)Y = Y - T \tag{6}$$

Since disposable income is equal to consumption plus personal saving $S$, we can use (5) and (6) to solve for saving plus taxes as a function of total income.

$$S + T = Y - C = [1 - a(1-t)]Y - b \tag{7}$$

We assume that investment depends linearly on the before-tax required quasi rent on capital $R(1-xt)/(1-vt)$ from equation (2) above:

$$I = g - h\left[\frac{1-xt}{1-vt}\right]R \tag{8}$$

Equating saving plus taxes from equation (7) to investment from equation (8) plus exogenous government spending $\overline{G}$, we find the equation of the $IS$ curve to be

$$R = \frac{(1-vt)}{(1-xt)}\left[\frac{b+g+\overline{G}}{h} - \frac{1-a(1-t)}{h}Y\right] \tag{9}$$

expected earnings before taxes and interest of a firm in some risk class $k$, $\tau$ is the tax rate, $R$ the interest payments on debt $D$ at rate $r$. Then the expected after-tax return to capital is

$$\begin{aligned}\overline{X}^{\tau} &= (1-\tau)(\overline{X}-R) + R \\ &= (1-\tau)\overline{X} + \tau R = (1-\tau)\overline{X} + \tau r D\end{aligned}$$

The value of the firm $V$ is then determined by capitalizing the uncertain stream $(1-\tau)\overline{X}$ at rate $\rho$, "the rate at which the market capitalizes the expected returns net of tax of an unlevered company of size $\overline{X}$ in class $k$," and by capitalizing the certain stream of tax savings on interest payments at rate $r<\rho$, or

$$V = \frac{(1-\tau)\overline{X}}{\rho} + \frac{\tau r D}{r} = \frac{(1-\tau)\overline{X}}{\rho} + \tau D$$

This expression can be manipulated to give the before-tax average cost of capital as

$$\frac{\overline{X}}{V} = \frac{1-\tau D/V}{1-\tau}\rho$$

where $D/V$ is the share of debt in the capital structure of the firm. This before-tax average cost of capital is also the marginal cost of capital $\rho^*$ with which the expected returns on new investments must be compared in making investment decisions, or

$$\rho^* = \frac{1-\tau L^*}{1-\tau}\rho$$

where $L^*$ is the firm's long-run target debt ratio. This is just equation (4) in different notation.

The slope of the *IS* curve is

$$(10)\quad \frac{\partial R}{\partial Y} = -\frac{(1-vt)}{(1-xt)}\left[\frac{1-a(1-t)}{h}\right] < 0$$

A change in the tax rate changes this slope for two reasons, both shown in equation (11): 1) the interest sensitivity of investment changes because of the term $(1-vt)/(1-xt)$, and 2) the multiplier changes because of the term $(1-a(1-t))/h$.

$$(11)\quad \frac{\partial^2 R}{\partial Y \partial t} = \left[\frac{1-a(1-t)}{h(1-xt)^2}\right] \cdot [v(1-xt) - x(1-vt)] - \frac{a(1-vt)}{h(1-xt)}$$

The first term in (11) can be either positive or negative, depending on whether the taxable fraction of profit $v$ is greater or less than the deductible fraction of capital costs $x$, while the second term is always negative.[3]

In Figure 1, the initial equilibrium of the system is given by the solid curves $IS_0$ and $LM_0$, with $IS_0$ derived from the solid curves in the other three quadrants. The effects of monetary policy are shown by a shift from $LM_0$ to $LM_1$ in response to an open market operation.

If the personal and corporate tax rates are reduced, leakages will be lower, as shown by the dashed flatter $S+T$ curve in the southeast quadrant. Thus the multiplier will be larger, and the *IS* curve will become flatter because of this effect, raising the effectiveness of monetary policy. The interest sensitivity of investment shown in the northwest

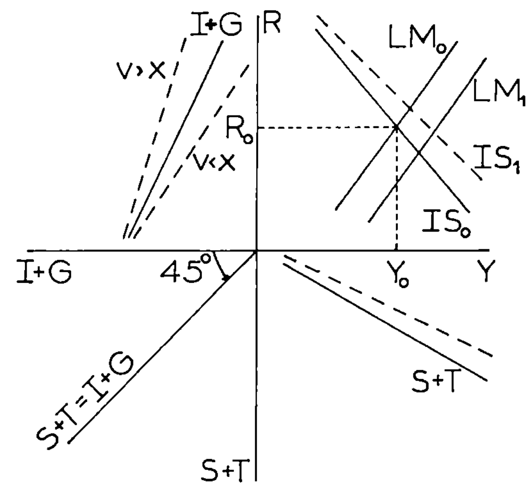

FIGURE 1. EFFECT OF REDUCTION IN RATE OF INCOME TAX

quadrant will either rise or fall, depending on whether $v<x$ (the right-hand dashed curve) or $v>x$ (the left-hand dashed curve). The case $v<x$ makes for a flatter *IS* curve and more effective monetary policy, while the case $v>x$ makes for a steeper *IS* curve and less effective monetary policy. The argument following equation (3) above indicated that $v<x$ for owner-occupied residential housing and other credit-financed consumer durables. On the other hand, $v>x$ for business investment. If $v=x$, the investment function does not shift with the changes in the tax rate.

Presumably, the combined effect of these shifts in the savings and investment functions will be a flatter *IS* curve shifted to the right, as $IS_1$. The presumption is that expression (11) is negative overall. Nevertheless, the effects of higher interest rates on business investment have been shown to be *greater* with high tax rates than with lower tax rates, contradicting Smith's view cited earlier.[4]

### III. Effects of Inflation

The preceding analysis has implicitly assumed a given price level. With an upward sloping Keynesian supply function, the

[3] This assumes that the debt-equity ratio is independent of the tax rate. If we allow the tax rate to affect the debt-equity ratio ($dx/dt>0$), the first term in (11) becomes

$$\frac{1-a(1-t)}{h}\left[\frac{v-x}{(1-xt)^2} - \frac{t(1-vt)}{(1-xt)^2}\cdot\frac{dx}{dt}\right]$$

The term in brackets is negative for $v<x$ and is positive for $v>x$ if $(v-x)/x(1-vt)>(t/x)(dx/dt)$. Thus a variable debt-equity ratio does not reverse our conclusions for the case $v>x$ unless the elasticity of the debt-equity ratio with respect to the tax rate exceeds 8 in the case of the *SMP* model ($v=1$, $x=.2$, $t=.5$).

[4] We have performed simulations with the *SMP* econometric model confirming this finding in the context of the model. A copy of these results is available to interested readers upon request.

analysis would have to be supplemented with discussion of the effects of higher prices on the results of Figure 1. The Keynes and Pigou effects, for example, would shift the curves $IS_1$ and $LM_1$ somewhat to the left as reduced real balances lead to a tighter money market and increased saving. However, the slopes would still change as shown in the figure.

More interesting possibilities arise if we assume that monetary expansion generates a higher rate of anticipated inflation. In this case the nominal rate of interest will rise above the real rate shown in Figure1. Indeed Jorgen Gelting has recently argued that the nominal rate of interest must rise above the real rate by *more* than the anticipated rate of inflation, because the income tax

> ". . . ignores the distinction between that part of interest payments which compensates for the fall in the value of money, and the part which is true income. If in non-inflationary conditions the equilibrium rate of interest gross of tax is 6 percent and thus net of 50 percent income tax is 3 percent then to obtain the same real rate of interest at 10 percent inflation, the market rate should rise to 26.6 percent, equivalent to 13.3 percent net of tax, which will leave a real rate of return of 3 percent. . . . More generally, assuming the rise in the market rate to compensate fully for inflation, the elasticity of the market rate with regard to the tax rate t will be t/(1−t). [p. 65]

Gelting is discussing the return on financial assets held by individuals who are suffering real capital losses ($G<0$ in equation (1)). In this case property taxes, the investment tax credit, and depreciation are irrelevant so the before tax yield is equal to

$$(12) \quad \frac{Q}{P} = \frac{1 - xt}{1 - vt} R + \frac{1 - zt}{1 - vt}(-G)$$

For personal investments, $x=0$, $v=1$, and $z=0$, giving

$$(13) \quad \frac{Q}{P} = \frac{1}{1 - t} R + \frac{1}{1 - t}(-G)$$

Given the real cost of capital $R$, an increase in the anticipated rate of inflation $(-G)$ will raise $Q/P$ by $1/(1-t)$ times the increase in the rate of inflation. It is obvious from equation (12) that this effect is due to the nondeductibility of the real capital losses caused by inflation. If the deductible fraction of losses $z$ were equal to the taxable fraction of yield $v$, a given rate of inflation would raise the nominal yield $Q/P$ by exactly the rate of inflation, unless the real rate of interest falls.

## IV. Concluding Comment

This investigation has shown that contemporary theories of investment behavior in which the cost of capital is taken to be a function of tax rates and the average cost of debt and equity capital yield new conclusions about the effect of taxes on investment behavior. Specifically, when the fraction of earnings that is taxable exceeds the fraction of the cost of capital that is deductible, an increase in the tax rate *raises* the interest sensitivity of investment demand. Conversely, when the taxable fraction of earnings falls short of the deductible fraction of costs, an increase in the tax rate *lowers* the interest sensitivity of investment demand.

There are two major unresolved issues to which our study points. First, the hypothesis that the rate of discount of future earnings prospects is a variable influenced by current market yields is a crucial hypothesis, and one with which we agree.

Secondly, the assumption that the relevant *marginal* cost of capital can be approximated by a weighted average of the *average* cost of debt and equity capital is equally important and much less acceptable. We are not alone in doubting this assumption, which has been questioned by John Lintner, Luigi Tambini, and Joseph Stiglitz, among others. All of these authors in one way or another raise James Duesenberry's argument that the marginal cost is increasing: "As debt rises relative to earnings the risk premium required to cover the leverage of debt service on earnings fluctuation will increase" (p. 94). Empirical evidence on this issue is provided by both Lintner and Tambini.

The effects of deleting the questionable assumption are unclear. A step in this direc-

tion has been taken by Stiglitz, who integrates the corporate and personal income taxes in a general equilibrium analysis of firms and investors.[5]

[5] Our colleague, Fred Westfield, has suggested another direction in which the analysis could be extended. Since the income tax also affects the factor cost of labor, it would be interesting to examine the substitution of capital for labor based on the production function.

# Separability and Vanishing Externalities

*By* W. David Montgomery*

In one of the most influential papers written on the subject of externalities, Otto Davis and Andrew Whinston argue that corrective taxes and private bargaining are likely to achieve an optimum in the presence of mutual externalities between two firms only when externalities are separable, in the sense that marginal cost is independent of the level of externality. Further analysis of the concept of separability reveals that even this conclusion is too optimistic. I shall argue below that the assumptions needed to make taxes and negotiations work properly rule out the possibility of having externalities in any observable situation.

The crucial step in Davis and Whinston's argument is the proposition that separability "... implies the game theoretic concept of dominance" (p. 247). They contend that when the cost function is separable, the profit-maximizing output of a firm affected by an externality is determined independently of the output choice of the firm causing the externality. Thus, when the process of mutual accommodation to externality is formulated as a noncooperative game, choosing that output level is a dominant strategy for the affected firm. Moreover, when the cost function is nonseparable, each firm must base its strategy on expectations about how the other firm will respond to its choices, and the game may fail to have an equilibrium point.

As stated by Davis and Whinston, the argument that separability of the cost function implies the existence of a dominant strategy is incorrect. A strategy should specify both inputs and outputs. In general, the functional relation between inputs and outputs depends on the level of externality. If the input combination which minimizes the cost to one firm of producing a fixed level of output changes as the output of the other firm changes, then it will not be true that the complete optimal strategy for one firm is independent of the actions of the other. The simplest example is the one input, one output case. Suppose an output $Y^*$ is optimal for firm 1 under all actions of firm 2, but that the input required to obtain this output varies as the output of firm 2 varies. Then firm 1 cannot decide on an input-output pair without knowledge of what firm 2 will do.

Separability of the cost function implies only that the output choice is independent of externality. A further condition is needed to guarantee that input choice is also independent. For input choice to be independent of externality, the marginal productivity of each input must be independent of the level of externality. If this is to be the case, the production function must also be separable. Writers following Davis and Whinston, including James Marchand and Keith Russell, have assumed that separability of the cost function is equivalent to separability of the production function. It will be established that this assumption is false, and that it is only possible to have separability of both functions in a special case. I will give two counter examples.

Let $C(Y_1, Y_2)$ be the cost function of a firm which produces $Y_1$ and suffers an external diseconomy which is a function of $Y_2$. The cost function is dual to a production function $F(X_1, \ldots, X_n, Y_2)$.

*Definition* 1: A cost function $C(Y_1, Y_2)$ is separable if and only if it can be written as $C_1(Y_1)+C_2(Y_2)$.

*Definition* 2: A production function $F(X_1, \ldots, X_n, Y_2)$ is separable if and only if it can be written as $g(X_1, \ldots, X_n) + h(Y_2)$.

* California Institute of Technology. I am indebted to Joel Franklin, David Grether, and James Quirk for substantial mathematical assistance and moral support. Research support was provided by the Environmental Quality Laboratory of the California Institute of Technology.

LEMMA 1: *A cost function is separable if and only if* $\partial^2 C/\partial Y_1 \partial Y_2 = 0$ *everywhere. A production function is separable if and only if* $\partial^2 F/\partial X_i \partial Y_2 = 0$, $i = 1 \ldots n$, *everywhere.*[1]

Consider the separable production function

$$F = X_1^{\alpha} X_2^{\beta} - h(Y_2)$$

where $\alpha+\beta<1$. We find the cost function by solving the cost-minimization problem and using the first-order conditions and the production function to eliminate the inputs from the cost equation. From the first-order conditons we have

$$\frac{W_1}{W_2} = \frac{\alpha X_2}{\beta X_1} \tag{1}$$

Solving for $X_1$ and substituting in the production function gives

$$Y_1 = X_2^{\alpha+\beta}\left(\frac{W_2\alpha}{W_1\beta}\right)^{\alpha} - h(Y_2) \tag{2}$$

Solving (2) for $X_2$, and substituting the resulting expression for $X_2$ in (1) enables us to express $X_1$ and $X_2$ in terms of $Y_1$ and $Y_2$ alone. Substitution in $C = W_1X_1 + W_2X_2$ gives the cost function

$$C = W_2\left(1 + \frac{\alpha}{\beta}\right)\left(\frac{W_2\alpha}{W_1\beta}\right)^{-\alpha/(\alpha+\beta)} \cdot (Y_1 + h(Y_2))^{1/(\alpha+\beta)} \tag{3}$$

Clearly (3) is not separable if $\alpha+\beta\neq 1$.

Now consider the nonseparable production function

$$F = (X_1 - h_1(Y_2))^{\alpha}(X_2 - h_2(Y_2))^{\beta}$$

A mathematical development similar to that of the first example yields the separable cost function

$$C = W_2\left(1 + \frac{\alpha}{\beta}\right)\left(\frac{\alpha}{\beta}\frac{W_2}{W_1}\right)^{-\alpha/(\alpha+\beta)} Y_1^{1/(\alpha+\beta)} + W_1h_1(Y_2) + W_2h_2(Y_2)$$

To find conditions under which the production function and its dual cost function are both separable, we express $\partial^2 C/\partial Y_1\partial Y_2$ in terms of the derivatives of the production function. We adopt the following abbreviations

$$\frac{\partial F}{\partial X_i} = F_i \qquad \frac{\partial F}{\partial Y_2} = F_Y$$

$$\frac{\partial^2 F}{\partial X_i \partial X_j} = F_{ij} \qquad \frac{\partial^2 F}{\partial X_i \partial Y_2} = F_{iY}$$

Let

$$\Delta = \begin{vmatrix} F_{11} \ldots F_{1n} & F_1 \\ \vdots \qquad \vdots & \vdots \\ F_{n1} \ldots F_{nn} & F_n \\ F_1 \ \ldots \ F_n & 0 \end{vmatrix}$$

Further let $\Delta_{ij}$ be the $i$, $j$th cofactor of $\Delta$.

THEOREM 1. *A cost function is separable if and only if it is derived from a production function which satisfies*

$$\sum_i F_{iY}\Delta_{n+1,i} + \Delta_{n+1,n+1}F_Y = 0 \tag{4}$$

*at every point which is a proper cost minimum.*[2]

It follows that the proper statement of the relation between separability and dominance is that separability of the cost function *and* of the production function implies the game-theoretic concept of dominance. Moreover, the two separability hypotheses are satisfied simultaneously only when the private part $g$ of the production function has a specific form.

COROLLARY 1: *If the cost function* $C(Y_1, Y_2)$ *and the production function* $F(X_1, \ldots, X_n, Y_2)$ *are both separable and* $F_Y\neq 0$ *everywhere, then* $|g_{ij}| = 0$, *where* $|g_{ij}|$ *is the Hessian determinant of* $g$.

PROOF:

By separability of the cost function (4) holds. Separability of the production function implies $F_{iY} = 0$ for all $i$. Therefore

[1] Lester Ford, p. 251, proves sufficiency. Necessity is trivial.

[2] For proof, see Appendix.

$$\Delta_{n+1,n+1} = \left| g_{ij} \right| = 0$$

COROLLARY 2: *If the cost function and production function are separable and $F_Y \neq 0$, then marginal cost $\partial C/\partial Y_1$ is constant in $Y_1$ and $Y_2$.*

PROOF:

From the Appendix and Paul Samuelson, p. 67,

$$\frac{\partial^2 C}{\partial Y_1^2} = \frac{\partial \lambda}{\partial Y_1} = \lambda \frac{\Delta_{n+1,n+1}}{\Delta} = 0$$

Constancy of marginal cost has some startling consequences. If no externality were present, then the supply function would be such that for any price of output greater than $\partial C/\partial Y_1$ the firm will produce unbounded output. At any price less than $\partial C/\partial Y_1$, it will produce zero output. Only when price of output equals $\partial C/\partial Y_1$ will the firm produce finite output. But when $C_2(Y_2) \neq 0$ there is a fixed cost, imposed on the firm by externality. Therefore even if price is exactly equal to $\partial C/\partial Y_1$ (which is a constant function of $Y_1$ and independent of $Y_2$), the firm will be losing money and will produce zero output But if price is at all higher than $\partial C/\partial Y_1$, the firm can earn unbounded profits by producing infinite output. Thus no equilibrium involving finite, nonzero output by a firm which suffers from an externality and has separable cost and production functions can exist unless the firm which causes the externality is producing zero output.

That is, when the conditions for the existence of dominant strategies in a two-firm externality game are satisfied, the only equilibrium possible is one in which one of the firms is out of business. It follows that it is impossible ever to observe a firm with separable cost and production functions suffering an externality, since either it or the firm causing the externality will always be driven out of business in equilibrium. If each firm creates an externality affecting the other, then only one can survive in equilibrium, and it will not suffer or cause any externality in equilibrium. Moreover, if the two firms produce the same output from the same input, this equilibrium is a Pareto optimum. Since the marginal costs of all firms are constant by hypothesis, one firm can produce any output as efficiently as many. The fixed cost imposed by externality implies that when more than one firm is in operation, more input is needed to produce a given output than is needed when only one firm operates.

The consequence of this analysis is the intensification of the pessimism expressed by Davis and Whinston regarding the possibility of using either corrective taxes or private bargaining to correct externalities. The only circumstances in which they thought such policies workable define a vacuous case, one in which externalities will never be observed or need to be remedied.

## Appendix

### *Proof of Theorem 1*

By Lemma 1 the cost function is separable if and only if $\partial^2 C/\partial Y_1 \partial Y_2 = 0$. We express $\partial^2 C/\partial Y_1 \partial Y_2$ in terms of the production function as follows. Form the Lagrangian expression

$$L = \sum_i W_i X_i + \lambda(Y_1 - F(X_1 \ldots X_n, Y_2))$$

First-order conditions are

$$W_i - \lambda F_i = 0$$

$$Y_1 - F = 0$$

We perturb the solution by varying $Y_1$ and $Y_2$. Totally differentiating the first-order conditions gives the system of equations

$$\text{(A1)} \quad \begin{bmatrix} F_{11} & \ldots & F_{1n} & F_1 \\ \vdots & & \vdots & \vdots \\ F_{n1} & \ldots & F_{nn} & F_n \\ F_1 & \ldots & F_n & 0 \end{bmatrix} \begin{bmatrix} dX_1 \\ \vdots \\ dX_n \\ d\lambda/\lambda \end{bmatrix} = \begin{bmatrix} \dfrac{dW_1}{\lambda} - F_{1Y} dY_2 \\ \vdots \\ \dfrac{dW_n}{\lambda} - F_{nY} dY_2 \\ dY_1 - F_Y dY_2 \end{bmatrix}$$

Solving for $dX_k$ using Cramer's rule gives

$$dX_k \frac{1}{\Delta}\left\{ \sum_{i=1}^{n}\left[\left(\frac{dW_i}{\lambda} - F_{iY}dY_2\right)\Delta_{ik}\right] + (dY_1 - F_Y dY_2)\Delta_{n+1,k}\right\}$$

We assume that $F$ is strictly quasi concave in $X_1 \ldots X_n$, so that $\Delta \neq 0$. Then

$$\frac{\partial X_k}{\partial Y_2} = \frac{-\sum_i F_{iY}\Delta_{ik} - F_Y\Delta_{n+1,k}}{\Delta}$$

Since

$$\frac{\partial C}{\partial Y_2} = \sum_k W_k \frac{\partial X_k}{\partial Y_2} \quad \text{and} \quad W_k = \lambda F_k,$$

$$\frac{\partial C}{\partial Y_2} = \frac{1}{\Delta}\left\{ -\sum_{i=1}^{n}\left[F_{iY}\lambda\left(\sum_k F_k\Delta_{ik}\right)\right] - \lambda F_Y \sum_k F_k \Delta_{n+1,k}\right\}$$

But $\sum_k F_k\Delta_{n+1,k} = \Delta$, and $\sum_k F_k\Delta_{ik} = 0$ since it is an expansion by alien cofactors. Therefore

$$\text{(A2)} \qquad \frac{\partial C}{\partial Y_2} = -\lambda F_Y$$

Differentiating (A2) with respect to $Y_1$ gives

$$\frac{\partial^2 C}{\partial Y_2 \partial Y_1} = -\lambda \sum_i F_{iY}\frac{\partial X_i}{\partial Y_1} - F_Y \frac{\partial \lambda}{\partial Y_1}$$

From (A1),

$$\frac{\partial \lambda}{\partial Y_1} = \lambda\frac{\Delta_{n+1,n+1}}{\Delta}, \qquad \frac{\partial X_i}{\partial Y_1} = \frac{\Delta_{n+1,i}}{\Delta}$$

Therefore

$$\frac{\partial^2 C}{\partial Y_2 \partial Y_1} = -\frac{\lambda}{\Delta}\left(\sum_i F_{iY}\Delta_{n+1,i} + \Delta_{n+1,n+1}F_Y\right)$$

# Estimated Parameters as Dependent Variables

By GARY R. SAXONHOUSE*

Judith Lave and Lester Lave, in their article in this *Review*, have proposed two imaginative, if simple, techniques for estimating cost functions in multiproduct, multiservice industries. Both techniques rest on the assumption that output mix varies among firms but is constant over time within any one firm. The first proposed technique involves two stages of analysis and allows a simple cost function to differ among firms. In the first stage a cost function is estimated for each firm. In the second stage a search is made for the factors causing variation among the estimated individual firm cost function parameters. The second proposed technique is based on the more limited assumption that, apart from the intercept term, all firms have the same cost function. Here the data are pooled and a single cost function estimated.

Lave and Lave, in the course of analysis, conclude that their dichotomous first technique is too inflexible, given their particular problems and opt for the second method. Despite their discarding of the first technique, others have been tempted to try it out and I think some discussion of this proposed estimation procedure is in order.[1] I think this discussion will also have some bearing on the Laves' second method.

The Laves' search for the causes of variation among individual cost functions involves taking firm cost function parameters and regressing them on various sets of independent variables in an effort to find significant relationships. Research workers using such a procedure should be aware that it is unusual in that before these regressions are ever run, an estimate of the variance of each dependent variable is available. Such knowledge may well be unpleasant. If on testing the hypothesis of homogeneity of variance using likelihood ratio methods, the null hypothesis is rejected, then the problem of heteroscedasticity in regressions using estimated parameters as dependent variables must be confronted. The now classical results indicate that applying ordinary least squares to an equation with a heteroscedastic error structure, while giving unbiased estimates of the coefficients of the independent variables, is nonetheless an inefficient method. Also, using the usual formula to calculate sampling variances may well involve an overstatement of the true sampling variances. Given the comparatively low $t$-statistics reported in the Laves' Tables 1, 2, and 3, the possibility exists that many of the variables reported as significant were really not at all significant.

What can be done about this problem of heteroscedasticity? Since estimates of the variance of each observation on the dependent variable are available, a straightforward procedure would imply weighting each observation on all variables used in the second-stage equation by the inverse of the estimated standard error of the dependent variable. This weighting technique, of course, is nothing more than an application of generalized least squares, where an estimate of the variance-covariance matrix is used in place of the true variance-covariance matrix.

One may well wonder whether the two-stage procedure is necessary at all. After all in the Laves' case, the linear second-stage equation (4) can easily be substituted into the linear first-stage equation (3). Unfortunately, to the extent that the variances of the stochastic terms in the first-stage cost equations are hospital specific, the fundamental equation resulting from this substitution will still contain a heteroscedastic error structure. Interestingly enough,

* The University of Michigan. I would like to thank Takeshi Amemiya for good advice and Judith Lave and Lester Lave for providing the data used in the analysis in this paper.

[1] See for example, J. G. Williamson. With increased interest in the last ten years in models where it is assumed that the parameters have a stochastic component, it is not surprising that there also be increased interest in models where the parameters are subject to systematic variation.

efficient estimation of this equation is nothing more than the generalized least squares estimation procedure suggested in the last paragraph![2] Efficient estimation of this equation is the same as applying ordinary least squares to the first-stage equation followed by estimating the second-stage equations using weighted least squares (see the Appendix).

This result is especially interesting since some of the Laves' pooled regressions (especially (4-3) and (4-4)) can be interpreted as resulting from the above suggested substitution. Thus, if it is assumed that the variances of the stochastic terms in these latter regressions are again hospital specific, then efficient estimation will require substantively the same two-stage approach. Efficient estimation in the presence of heteroscedasticity requires modifications in both the Laves' proposed techniques which make them virtually identical.

Table 1 presents the results of the likelihood ratio test on the hypothesis of homogeneity of sampling variance for each of the four estimated first-stage coefficients.[3] In each instance the null hypothesis cannot be accepted. Heteroscedasticity may well be present and it is appropriate to use the weighting procedure outlined above. Thus, each of the Laves' regressions have been run again using this method. The results are presented in Tables 2, 3, and 4. Inspection of the tables indicates the extent to which use of the classical least squares formula to calculate the sampling variance in the presence of the type of heteroscedasticity described above will underestimate the variance. The underestimation varies from none at all to 65 percent. On the average, it is 40 percent. The gains in efficiency which result from the application of the suggested generalized least squares procedure also appear to be substantial. While the actual sampling variances, of course, are not available, the estimated sampling variances under the new procedures are from 40 to 80 percent lower than the correct estimates of the least squares sampling variances. On the average they are 55 percent lower.

TABLE 1—TESTING FOR HOMOGENEITY OF VARIANCE

| Hypothesis[b] | Test Statistic[a] |
|---|---|
| $\sigma^2_{a1T}=\sigma^2_{a2T}=\ldots=\sigma^2_{a74T}$ | $436.352>110.781$ |
| $\sigma^2_{a1U}=\sigma^2_{a2U}=\ldots=\sigma^2_{a74U}$ | $523.187>110.781$ |
| $\sigma^2_{a1F}=\sigma^2_{a74F}=\ldots=\sigma^2_{a74F}$ | $314.586>110.781$ |
| $\sigma^2_{a1S}=\sigma^2_{a2S}=\ldots=\sigma^2_{a74S}$ | [c] $>110.781$ |

[a] $110.781=5$ percent critical value

[b] $\sigma^2_{aij}$=sampling variance on $i$th estimate of $j$th coefficient

[c] Test statistic was too large for the computer to print it out.

While some of the point estimates presented in Tables 2–4 differ substantially from the Laves' estimates, the basic character of the results remains the same. Substantive alteration of their results does occur when regressions having the estimated size coefficient as the dependent variable are run using the new procedure. The new generalized least squares estimates are presented in Table 5. Using ordinary least squares techniques, the Laves are unable to find any variables which significantly contribute to the explanation of the variation of the size coefficient. Similarly, the size coefficient is insignificant in each of the Laves' four pooled regressions. Contrary to both these results,

[2] This result is more than a curiosum. It suggests that attempting to explain the variation among parameter estimates is not the crude *ad hoc* procedure it might appear at first glance. Rather, if appropriate allowance is made for the possible presence of heteroscedasticity (using the weighting procedures outlined above), such regressions are the legitimate second step in an efficient generalized least squares estimation of what could typically be more elaborate models. Given the computational advances of recent years, the literature is full of articles containing many time-series regressions separately estimated under identical specification for firms, industries, states, regions, and nations (or alternatively containing many cross-sections also separately estimated at varying points in time under identical specifications). The above results suggest that efficient systematic explanation of the reported intersample results need not require the underlying raw data (at least this would be true under the specification suggested in Appendix). Only the published parameter estimates and their sampling variances together with a set of second-stage explanatory variables are necessary for the elaboration and estimation of the conceptually richer framework.

[3] The likelihood ratio test on the homogeneity of variance hypothesis is described in P. Hoel, pp. 225–28.

[a] In the event that the constant term in the unweighted regression proved insignificant, it was suppressed in the weighted regression. This was done in order to avoid possible spurious correlation. For those weighted regressions where this was not possible, the calculated coefficient of determination must be treated with care.

*Note:* $\hat{a}_i$ ≡ estimated first-stage parameter
$AC_0$ ≡ cost per patient day in the initial period
$S_0$ ≡ number of beds in the initial period
$U_0$ ≡ hospital occupancy rate

Italicized coefficient significant at .05 level.

the new generalized least squares in Table 5 present a variety of significant explanatory variables.[4] The estimated size coefficients do not appear to be random numbers. Rather, variations in the coefficients are susceptible to systematic explanation. A change in the size of a hospital can significantly change average costs. Note for the time span considered, virtually all changes involved increases in hospital size. Thus the regressions in Table 5 suggest that increases in size will increase the average costs of already relatively large hospitals, hospitals with high initial average costs and hospitals in Pittsburgh, while reducing the average costs of advanced teaching hospitals and hospitals which, prior to expansion, have relatively high rates of utilization. While the results are quite plausible, especially when initial average costs and initial rates of utilization are taken as proxies for overall managerial competence, they should nonetheless be regarded with care. Only the coefficient on $\log U_0$ seems almost completely impervious to change in specification. Nonetheless, the

[4] When the Laves' pooled regressions are reestimated with the generalized least squares approach suggested here, allowing for heteroscedasticity, the size coefficient likewise becomes significant. For example, when (4−1) is reestimated we find

$$\log I = -\underset{(16.29)}{.458} \log J + \underset{(5.24)}{.122} \log K + \underset{(67.8)}{.056}t + \underset{(22.6)}{.067}F$$

## APPENDIX

Let the Laves' first-stage and second-stage equations be given by

$$\text{(A1)} \quad y_j = X_j a_j + u_j, \qquad j = 1, 2, \ldots, 74$$

$$\text{(A2)} \quad a_j = Z_j b, \qquad j = 1, 2, \ldots, 74$$

where $a_j$ and $b$ are 4-component and (4x$G$)-component vectors of known parameters, $X_j$ is a 14x4 matrix of known constants, $Z_j$ is defined as diag $(z_j, z_j, \ldots, z_j)$ where $z_j$ is a $G$-component vector of known constants and $u_j$ is a 14-component vector of observable random variables with zero means and variance-covariance matrix given by

$$\text{(A3)} \quad \begin{aligned} E(u_j u_k) &= \lambda_{jj} I_{14} && \text{when } j = k \\ &= 0 && \text{when } j \neq k \end{aligned}$$

The term $\lambda_{jj}$ is defined as being scalar.

In what follows it will be assumed that $X$ and $Z$ are such that every matrix that must be inverted is indeed invertible.

Consider now the estimation of $a_j$ and $b$ assuming the $\lambda_{jj}$ are known. Given that the $\lambda_{jk}$, $k \neq j$ are equal to zero, best linear unbiased estimates of the $a_j$ will be simply given by

$$\text{(A4)} \quad \hat{a}_j = (X_j' X_j)^{-1} X_j' y_j, \qquad j = 1, 2, \ldots, 74$$

From (A2), (A3), and (A4) it follows that

$$\text{(A5)} \quad \hat{a}_j = Z_j b + \{X_j' [\lambda_{jj} I]^{-1} X_j\}^{-1} X_j' (\lambda_{jj} I)^{-1} u_j \qquad j = 1, 2, \ldots, 74$$

The term $\hat{b}$ can be defined as the best linear unbiased estimator for (A5) such that

$$\text{(A6)} \quad \hat{b} = \left\{\sum_{j=1}^{74} Z_j' [X_j' (\lambda_{jj} I_{14})^{-1} X_j] Z_j\right\}^{-1} \cdot \left\{\sum_{j=1}^{74} Z_j' X_j' [\lambda_{jj} I_{14}]^{-1} y_j\right\}$$

Another approach would be to combine (A1) and (A2) as

$$\text{(A7)} \quad y_j = X_j Z_j b + u_j \qquad j = 1, 2, \ldots, 74$$

It is apparent that the best linear unbiased estimator of $b$ will be given by $b^*$

$$\text{(A8)} \quad b^* = \left\{\sum_{j=1}^{74} Z_j' X_j' [\lambda_{jj} I_{14}]^{-1} X_j Z_j\right\}^{-1} \cdot \left\{\sum_{j=1}^{74} Z_j' X_j' [\lambda_{jj} I_{14}]^{-1} y_j\right\}$$

Equations (A6) and (A8) are identical

$$\begin{aligned} \hat{b} &= \left\{\sum_{j=1}^{74} Z_j' [X_j' (\lambda_{jj} I_{14})^{-1} X_j] Z_j\right\}^{-1} \cdot \left\{\sum_{j=1}^{74} Z_j' [X_j' (\lambda_{jj} I_{14})^{-1} X_j] \hat{a}_j\right\} \\ &= \left\{\sum_{j=1}^{74} Z_j' [X_j' (\lambda_{jj} I_{14})^{-1} X_j] Z_j\right\}^{-1} \cdot \left\{\sum_{j=1}^{74} Z_j' \left(\frac{1}{\lambda_{jj}}\right) X_j' X_j (X_j' X_j)^{-1} X_j y_j\right\} \\ &= \left\{\sum_{j=1}^{74} Z_j' [X_j' (\lambda_{jj} I_{14})^{-1} X_j] Z_j\right\}^{-1} \end{aligned}$$

$$\cdot \left\{ \sum_{j=1}^{74} Z_j' X_j' (\lambda_{jj} I_{14})^{-1} y_j \right\}$$
$$= b^*$$

In the present case where $\lambda_{jj}$ is unknown it can be estimated by

$$\text{(A9)} \quad \hat{\lambda}_{jj} = \frac{1}{14} (y_j - X_j \hat{a}_j)'(y_j - X_j \hat{a}_j)$$

Such estimates can be easily shown to be consistent (as sample size approaches infinity) under general conditions. An estimate of $b$ can be obtained by substituting $\hat{\lambda}_{jj}$ in (A6) and (A8). The estimate of $b$ obtained from such a substitution will have the same asymptotic distribution as $\hat{b}$ or $b^*$.

# The Foundations of Money Illusion in a Neoclassical Micro-Monetary Model: Comment

By ROBERT W. CLOWER AND JOHN G. RILEY*

Considering the attention that economists have devoted to monetary neutrality and related phenomena in recent years, it would be remarkable if, as Richard Dusansky and Peter Kalman (hereafter D-K) have recently suggested,[1] the microfoundations of money illusion were not now well established. In truth, D-K's suggestion appears to reflect a flaw in their understanding of the problem rather than a gap in received doctrine. Our purpose in this comment is to set the record straight by restating and qualifying D-K's results.

Modifying slightly the notation of D-K (pp. 115–16), we start by supposing that the demand functions of a typical household are defined as solutions, $\bar{x}(p, y, L)$, $\bar{m}(p, y, L)$ of the Patinkinesque utility maximization problem,

$$\text{(1)} \qquad \text{Max } u = f(x, m, p)$$

subject to $px+m-y-L=0$

If we suppose that the preference function $f$ satisfies *only* the usual continuity and convexity assumptions, then it is obvious (though D-K take two pages to show this) that the functions $\bar{x}$ and $\bar{m}$ *may* exhibit money illusion in the sense of Don Patinkin; i.e., in general, the functions $\bar{x}$ and $\bar{m}$ will *not* be homogeneous of degree zero and one, respectively, in the variables $p$, $y$, and $L$.[2] As is well known, however, a sufficient condition for absence of money illusion in the functions defined by (1) is that the preference function $f$ be homogeneous of degree zero in the variables $m$ and $p$, which is simply to say that, in Paul Samuelson's words, "... money is evaluated only in terms of the work which it has to do" (1947, p. 119).[3]

This condition can be weakened mathematically by requiring only that

$$\text{(2)} \qquad f(x, \lambda m, \lambda p) = \lambda^k f(x, m, p)$$

which is logically equivalent to the inelegant sufficiency conditions that D-K work out so laboriously in their paper (pp. 118–20).[4] But the "generality" thus achieved is spurious, since the conventional assumption that $f$ is homogeneous of degree zero already serves completely to characterize the class of illusion-free demand functions that are derivable from ordinal preference functions.[5] To see this, note that setting $\lambda=1/p_1$ in (2) and rearranging gives us

$$\text{(3)} \qquad f(x, m, p) = p_1^k f(x, m/p_1, p/p_1)$$

Clearly, all marginal rates of substitution, and hence all "real" demand functions, depend only on $f(x, m/p_1, p/p_1)$, which is homogeneous of degree zero in $m$ and $p$. Thus D-K's attempt to clarify the foundations of money illusion—which starts with an

* Professor of economics and assistant professor of economics, respectively, University of California, Los Angeles. We are grateful to Peter W. Howitt of the University of Western Ontario and to Roger Kormendi of UCLA for helpful suggestions.

[2] See Patinkin, pp. 22–23.

[3] See also Samuelson (1968), p. 8.

[4] The equivalence follows from the elementary fact (apparently overlooked by D-K) that a function is homogeneous of degree $k$ in some subset of variables if and only if its partial derivatives are homogeneous of the same degree with respect to variables excluded from, and of one lower degree with respect to variables included in the subset.

[5] Moreover, with the sufficiency condition expressed as in (2) above, it becomes clear that for all positive values of $k$ a proportional increase in prices and initial asset values increases the welfare of a household despite the fact that it chooses an identical bundle! While this implication is not subject to the usual market tests, one could pick households at random and ask each to make a bid on the option of receiving a proportional subsidy on the present value of assets and paying a tax at the same proportional rate on all purchases. D-K's generalization would be supported by nonzero bids on this option!

unwarranted criticism of Patinkin's classic account of the problem (compare D-K, p. 117, with Patinkin (1956), pp. 68–71, 313–14, and Patinkin (1965), pp. 78–79, 457–60) succeeds only in muddying water that was formerly clear.

A final remark is in order concerning D-K's discussion (pp. 120–22) of "testable implications" of illusion-free demand functions. Unlike the Hicksian symmetry conditions of conventional value theory, which follow directly from standard continuity assumptions, all of D-K's symmetry implications require strong restrictions on the form of the utility function—conditions to which D-K refer obliquely in footnotes but nowhere state explicitly in their paper. Modifying a theorem due to Kalman and Michael Intriligator, it can be shown that these restrictions reduce to the requirement that $f(x, m, p)$ be expressible in the semi-separable form[6]

$$f(x, m, p) = f_1(p)f_2(x, m) + f_3(p) \tag{4}$$

With this arbitrary and implausible requirement imposed as a maintained hypothesis, it would be disingenuous (to put it mildly) to suggest that empirical investigation of symmetry conditions might serve to establish the presence or absence of illusion-free demand functions.

[6] Kalman and Intriligator obtain the form

$$f(x, m, p) = g(x, m) + h(p) + \alpha(px + m)$$

However, to make this consistent with the D-K assumptions we must require either that $\alpha = 0$ or that $f$ be homogeneous of degree one in $m$ and $p$. Assuming the former allows the additional generality of (2).

# The Foundations of Money Illusion in a Neoclassical Micro-Monetary Model: Comment

By C. Robert Wichers*

In an interesting and valuable article in this *Review*, Richard Dusansky and Peter Kalman (D-K) recently discussed the foundations of money illusion in a neoclassical micro-monetary model. Their micro-monetary model specifies a utility function depending on the quantities of all commodities and of money, as well as on all commodity prices. Maximization of the utility function subject to a conventional budget constraint leads to demand functions: Dusansky and Kalman's main result is the formulation of two conditions that are sufficient to render all demand functions free of money illusion.

In the present paper, D-K's result is extended in two ways. First, the sufficient conditions for illusion-free demand functions are weakened. This is done in Section I. Second, the validity of the D-K result is extended to supply functions as well. This is done in Section II. Two conclusions are thereby reached. These conclusions differentiate between money and commodities. In Section III, the origin of this differentiation is traced. It is found that money appears different from commodities (in the D-K model) only because it serves as the unit of account. Thus, money illusion is, in fact, numeraire illusion.

## I

The Dusansky-Kalman model requires that

$$u = f(x_1, \ldots, x_{n-1}, m; p_1, \ldots, p_{n-1}) = f(x, m; p)$$

be maximized, subject to the budget constraint

$$b = \sum_1^{n-1} p_i x_i + m$$

* Assistant professor of economics, State University of New York, Stony Brook. I am indebted to an anonymous referee for a number of helpful suggestions.

Here $x = \{x_1, \ldots, x_{n-1}\}$ is the vector of purchased commodity quantities; $p = \{p_1, \ldots, p_{n-1}\}$ is the (positive) vector of associated prices; $m$ represents money holdings at the end of the period; $b$ is the sum of money holdings at the beginning of the period and income during the period. (D-K use separate symbols for the two components of $b$. Since, however, only the sum of the components plays a role in what follows, and not the components individually, there is no harm in using $b$.) To avoid corner solutions, the $x_i$ and $m$ are taken to be positive. The utility function is assumed so that a constrained maximum exists, and so that the demand functions are unique in a neighborhood of the maximizing solution or solutions.

Let $(\bar{x}_1, \ldots, \bar{x}_{n-1}, \bar{m})$ maximize the utility function, subject to the budget constraint. Then these first-order conditions hold at $(\bar{x}_1, \ldots, \bar{x}_{n-1}, \bar{m})$:

$$\frac{\partial}{\partial x_i} f(x, m; p) = \lambda p_i \qquad i = 1, \ldots, n-1$$

$$\frac{\partial}{\partial m} f(x, m; p) = \lambda$$

$$b = \sum_1^{n-1} p_i x_i + m$$

Here $\lambda$ is the value assumed by the usual Lagrange multiplier. Solving the first-order conditions gives the locally unique demand functions

$$\bar{x}_i = \bar{x}_i(p, b) \qquad i = 1, \ldots, n-1$$
$$\bar{m} = \bar{m}(p, b)$$

By definition, the demand functions $\bar{x}_i(p, b)$ are illusion free if and only if they are homogeneous of degree zero in $p$ and $b$.

Dusansky and Kalman's main result is now:

(1) if all $\partial f(x, m; p)/\partial x_i$ are homogeneous of any degree $k$ in $m$ and $p$, and
(2) if $\partial f(x, m; p)/\partial m$ is homogeneous of degree $k-1$ in $m$ and $p$, then
(3) the demand functions are illusion free, and
(4) $\bar{m}(p, b)$ is homogeneous of degree 1 in $p$ and $b$.

The proof given by Dusansky and Kalman is ingenious, and far from easy. A slight artifice yields a simpler proof, which, moreover, leads immediately to weakened versions of conditions (1) and (2).

The artifice consists of introducing two $n$-vectors, $P=\{P_1, \ldots, P_n\}$ and $X=\{X_1, \ldots, X_n\}$, defined by

$$\{P_1, \ldots, P_n\} = \{p_1, \ldots, p_{n-1}, b\} \quad \text{and}$$
$$\{X_1, \ldots, X_n\} = \{x_1, \ldots, x_{n-1}, m/b\}$$

It is easy to see that

$$m = bX_n = P_nX_n \tag{5}$$

The utility function, $f(x, m; p)$, may now be written as $f(X_1, \ldots, X_{n-1}, P_nX_n; p)$, hence as $g(X_1, \ldots, X_{n-1}, X_n; p, P_n)$, that is, $g(X; P)$:

$$f(x, m; p) = g(X; P)$$

A useful and readily verified result is

$$f(x, am; ap) = g(X; aP) \qquad \text{(any scalar } a \neq 0) \tag{6}$$

The budget constraint

$$b = \sum_1^{n-1} p_ix_i + m \quad \text{becomes}$$

$$P_n = \sum_1^{n-1} P_iX_i + P_nX_n$$

or $$P_n = \sum_1^{n} P_iX_i$$

D-K's main result, (1)–(4), will now be reformulated in terms of $X$ and $P$, and then proved. After that, conditions (1) and (2) are weakened.

Condition (1) says that for $i=1, \ldots, n-1$, $\partial f(x, am; ap)/\partial x_i = a^k \partial f(x, m; p)/\partial x_i$. By (6), this is equivalent to $\partial g(X; aP)/\partial X_i = a^k\partial g(X; P)/\partial X_i$. Condition (2) says that $\partial f(x, am; ap)/\partial(am) = a^{k-1}\partial f(x, m; p)/\partial m$ or $\partial f(x, am; ap)/\partial m = a^k \partial f(x, am; p)/\partial m$. By (5) and (6), this may be written as $\partial g(X; aP)/\partial(P_nX_n) = a^k\partial g(X; P)/\partial(P_nX_n)$, and hence as $\partial g(X; aP)/\partial X_n = a^k \partial g(X; P)/\partial X_n$.

Conclusion (3), $\bar{x}_i(ap, ab) = \bar{x}_i(p, b)$, becomes $\bar{X}_i(aP) = \bar{X}_i(P)$, $i=1, \ldots, n-1$. Conclusion (4) says that $\bar{m}$, which by (5) equals $b\bar{X}_n$, is homogeneous of degree 1 in $p$ and $b$. Thus, $\bar{X}_n$ is homogeneous of degree zero in $p$ and $b$, or $\bar{X}_n(aP) = \bar{X}_n(P)$.

Combining results gives this restatement of (1)–(4): if $\partial g(X; aP)/\partial X_i = a^k\partial g(X; P)/\partial X_i$ for some $k$, all $a \neq 0$, and $i-1, \ldots, n$, then $\bar{X}_i(aP) = \bar{X}_i(P)$ for $i=1, \ldots, n$. For notational convenience, denote $\{\partial g/\partial X_1, \ldots, \partial g/\partial X_n\}$ by grad $g(X; P)$, and $\{\bar{X}_1(\ ), \ldots, \bar{X}_n(\ )\}$ by $\bar{X}(\ )$. The statement then becomes

(7) if grad $g(X; aP) = a^k$ grad $g(X; P)$ for some $k$ and all $a \neq 0$,
(8) then $\bar{X}(aP) = \bar{X}(P)$.

This is the D-K result, translated in terms of $g$, $X$, and $P$. Its proof is given in the next paragraph.

Since the vector $\bar{X}$ maximizes $g(X; P)$ subject to the budget constraint $P_n = \sum_1^n P_iX_i$, the elements of $\bar{X}$ satisfy the first-order conditions

$$\text{grad } g(X; P) = \lambda P \tag{9}$$

$$P_n = \sum_1^n P_iX_i \tag{10}$$

Equation (9) may be read as: the vectors grad $g(X; P)$ and $P$ are collinear. Let now $P$ be multiplied by $a \neq 0$. In view of (7), grad $g(X; P)$ is then multiplied by $a^k$. Since $a$ and $a^k$ are scalars, multiplication by $a$ preserves the collinearity of grad $g(X; P)$ and $P$, thus replacing (9) with an equivalent statement. Obviously, multiplication of $P$ by $a$ will replace (10), too, with an equivalent

statement. It follows that the solution $\bar{X}$ of (9), (10) is left invariant, proving (8). The proof of (7)–(8) and, hence, of (1)–(4) is thereby completed.

The proof requires less than D-K's, which is based on the assumption that the constrained utility maximum is regular, as well as on the assumption that the utility function is twice differentiable.

The preceding suggests a way of weakening (1) and (2), the sufficient conditions for illusion-free demand functions. Clearly, the crux of the proof is that multiplication of $P$ by $a$ preserves the collinearity of the vectors grad $g(X; P)$ and $P$. It would therefore be sufficient to require that multiplication of $P$ by $a$ turn grad $g(X; P)$ into a nonzero multiple of itself; it would even suffice if grad $g(X; P)$ became the sum of (i) such a multiple and (ii) a multiple of $P$.

Formalizing, we require—instead of (7)—that there exist two functions, $h_1(a)$ and $h_2(a)$, wholly arbitrary except for the condition that $h_1(a)\neq 0$ when $a\neq 0$, and such that

$$\text{(11)}\quad \text{grad } g(X; aP) = h_1(a)\cdot \text{grad } g(X; P) + h_2(a)\cdot P \qquad \text{for all } a \neq 0$$

Reverting to initial notation yields the sought for, weakened version of (1) and (2), and hence a generalization of the entire statement (1)–(4):

If, for some $h_1(a)$ and $h_2(a)$, with $h_1(a)\neq 0$ when $a\neq 0$, one has both

$$\text{(12)}\quad \frac{\partial}{\partial x_i} f(x, am; ap) = h_1(a)\frac{\partial}{\partial x_i} f(x, m; p) + h_2(a)p_i \qquad \text{for all } a \neq 0 \text{ and all } i, \quad \text{and}$$

$$\text{(13)}\quad \frac{\partial}{\partial(am)} f(x, am; ap) = \frac{1}{a}h_1(a)\frac{\partial}{\partial m} f(x, m; p) + \frac{1}{a}h_2(a)b \qquad \text{for all } a \neq 0$$

(14) then all demand functions are illusion free, and

(15) $\bar{m}(p, b)$ is homogeneous of degree 1 in its arguments.

Setting $h_1(a)=a^k$ and $h_2(a)=0$ gives back (1)–(4).

## II

Both the Dusansky-Kalman result and its generalization (12)–(15) refer to demand functions only. Both are further generalized in the present section: their validity is extended to supply functions as well.

It may be recalled that $b=P_n$ represents money holdings at the beginning of the period, plus the amount of money acquired during the period. Let now $b_i$, $i=1, \ldots, n-1$, be the quantity of good $i$ possessed at the beginning of the period, plus the quantity of good $i$ exogenously acquired—that is, acquired in ways other than by trading—during the period. Introduction of $b_1, \ldots, b_{n-1}$ does not affect the utility function, which is still

$$f(x, m; p) = g(X; P)$$

The budget constraint does change; it becomes

$$\sum_1^{n-1} p_i b_i + b = \sum_1^{n-1} p_i x_i + m$$

reflecting that the value of initial holdings, including transfers, equals the value of eventual holdings. Using $P=\{p_1, \ldots, p_{n-1}, b\}$ and $X=\{x_1, \ldots, x_{n-1}, m/b\}$, and defining $B=\{B_1, \ldots, B_n\}$ as $\{b_1, \ldots, b_{n-1}, 1\}$, one can write the budget constraint also as

$$\sum_1^n P_i B_i = \sum_1^n P_i X_i$$

or

$$\sum_1^n P_i(X_i - B_i) = 0$$

For $i=1, \ldots, n-1$, the difference $x_i - b_i = X_i - B_i$ represents, when evaluated at $\bar{x}_i=\bar{X}_i$, either the individual's demand for good $i$ during the period or the individual's supply of good $i$ during the period, depending on whether $\bar{x}_i - b_i$ is positive or negative. Clearly, the demand for or supply of good $i$ is homogeneous of degree zero in $p$ and $b$ if and only if $\bar{x}_i$ $(=\bar{X}_i)$ is invariant un-

der scalar multiplication of the vector $P=\{p_1, \ldots, p_{n-1}, b\}$.

For $i=n$, $\overline{X}_i-B_i$ is $\overline{X}_n-B_n=\overline{m}/b-1$. Multiplication by $P_n(=b)$ gives $P_n(\overline{X}_n-B_n)=\overline{m}-b$. This quantity is, if positive, the amount of money acquired—through trading—during the period; if negative, it is the amount of money spent. It is convenient to call $\overline{m}-b$ the individual's demand for or supply of money during the period. This demand or supply is homogeneous of degree one in $p$ and $b$ if and only if $\overline{X}_n$ is invariant under scalar multiplication of $P$, as is easy to see.

The purpose of this section, it is recalled, is to extend both the D-K result and its generalization (12)–(15) to supply. The extension sought can now be formulated (and will be proved immediately after formulation):

If, for some $h_1(a)$ and $h_2(a)$, with $h_1(a)\neq 0$ when $a\neq 0$,

$$\text{(16)}\quad \operatorname{grad} g(X; aP) = h_1(a) \operatorname{grad} g(X; P) + h_2(a)P \quad \text{for all } a \neq 0$$

then $\overline{X}(aP)=\overline{X}(P)$

As noted, $\overline{X}(aP)=\overline{X}(P)$ implies that all commodity demand and supply functions are homogeneous of degree zero in $P$, and that the demand or supply function for money is homogeneous of degree one in $P$. In initial notation, (16) reads: if both $\partial f(x, am; ap)/\partial x_i=h_1(a)\partial f(x, m; p)/\partial x_i+h_2(a)p_i$ for all $a\neq 0$ and all $i$ and $\partial f(x, am; ap)/\partial(am)=(1/a)h_1(a)\partial f(x, m; p)/\partial m+(1/a)h_2(a)b$ for all $a\neq 0$, then $\bar{x}_i-b_i$ is homogeneous of degree zero in $p$ and $b$ $(i=1, \ldots, n-1)$, and $\overline{m}-b$ is homogeneous of degree one in the same variables.

For a proof, consider that $\overline{X}$ maximizes utility $g(X; P)$ subject to the budget constraint. That is to say, $\overline{X}$ satisfies the first-order conditions

$$\text{(17)}\quad \operatorname{grad} g(X; P) = \lambda P$$

$$\text{(18)}\quad \sum_1^n P_i(X_i - B_i) = 0$$

Let now $P$ be multiplied by some scalar $a\neq 0$. Equation (18) is then replaced with an equivalent statement, as is obvious. Equation (17), asserting the collinearity of grad $g(X; P)$ and $P$, is also replaced with an equivalent statement, for, as the condition in (16) implies, grad $g(X; aP)$ and $aP$ are collinear. It follows that multiplication of $P$ by $a$ does not affect the solution $\overline{X}$, which completes the proof.

For an application of (16), let the utility function be classically specified, as $u=f(x_1, \ldots, x_{n-1})$. This utility function contains neither money nor prices, and is therefore homogeneous (of degree zero) in money and prices. Thus, the condition in (16) is necessarily satisfied. (Formal confirmation is obtained by setting $h_1(a)\equiv 1$ and $h_2(a)\equiv 0$.) It follows that the conclusion of (16) holds. In words: if the utility function is classical, all commodity demand functions as well as all commodity supply functions are homogeneous of degree zero in $p_1, \ldots, p_{n-1}$, and $b$; furthermore, the demand or supply function for money is homogeneous of degree one in the same variables. For commodity *demand* functions, this result is familiar. Also, if all money is spent—as one would expect when no utility is assigned to money—final holdings will be zero, $\overline{m}=0$. The demand or supply function for money, $\overline{m}-b$, is then $-b$, which is indeed homogeneous of degree one in $p_1, \ldots, p_{n-1}, b$.

## III

Money is traditionally held to be different from commodities, and the conclusion of (16)—commodity demand and supply functions homogeneous of degree zero, demand or supply function for money homogeneous of degree one—is in agreement with that point of view. What is unusual is that (16) gives *mathematical* expression to the difference between money and commodities. This implies that, somewhere among the assumptions and definitions, a *mathematical* distinction between money and commodities must have been introduced. The purpose of the present section is to find out where this distinction was introduced, and in which form.

Dusansky and Kalman, who comment on this matter, attribute the observed differ-

ence between money and commodities to the fact that, in their approach, "... $m$ is a nominal variable, while the $x_i$ are real variables" (p. 120, fn. 5). This cannot be the reason, however, because D-K do not express either the nominal nature of $m$ or the real nature of the $x_i$ in mathematical terms. Their distinction between nominal and real variables is therefore wholly interpretive, and cannot give rise to the observed, mathematical difference between money and commodities. That difference must have a mathematical origin.

As it turns out, money is different—in the present context, at least—only because it serves as the unit of account. This will be proved in two ways. The first proof shows that, if a *commodity* is chosen as the numeraire, the demand or supply function for that commodity is homogeneous of degree one, whereas all other demand and supply functions, *including the one for money*, are homogeneous of degree zero. The second proof shows that if some nongood, such as the guinea, is chosen as the numeraire, *all* demand and supply functions are homogeneous of degree zero. The two assertions to be proved are not meant to imply (or deny) that the selection of a numeraire is a formality. The sole purpose of the proofs is to trace the origin of the observed, mathematical difference between money and commodities.

To simplify the discussion, let $x_n$ and $b_n$ replace $m$ and $b$. The utility function, thus far $f(x_1, \ldots, x_{n-1}, m; p_1, \ldots, p_{n-1})$, then becomes $f(x_1, \ldots, x_n; p_1, \ldots, p_{n-1})$, and the budget constraint

$$\sum_1^{n-1} p_i b_i + b = \sum_1^{n-1} p_i x_i + m$$

becomes

$$\sum_1^{n-1} p_i b_i + b_n = \sum_1^{n-1} p_i x_i + x_n$$

This may also be written as

$$\sum_1^{n} p_i b_i = \sum_1^{n} p_i x_i$$

since $p_n \equiv 1$ anyway.

Let now some commodity be chosen as the numeraire—good 1, say. It is assumed that money does not thereby cease to exist; that is, it is assumed that a good may be called "money" even if some *other* good serves as the unit of account. The arguments of the utility function now include $p_n$, the price of money in terms of good 1, but they do not include $p_1$, since $p_1 \equiv 1$. Thus, the utility function becomes $f(x_1, \ldots, x_n, p_2, \ldots, p_n)$. The budget constraint,

$$\sum_2^{n} p_i b_i + b_1 = \sum_2^{n} p_i x_i + x_1$$

may be written as

$$\sum_1^{n} p_i b_i = \sum_1^{n} p_i x_i$$

using $p_1 \equiv 1$. Comparison with the preceding paragraph shows that the budget constraint is left unchanged (formally at least) when the role of numeraire is transferred from good $n$ to good 1; only the utility function is affected. The utility function now depends on $p_n$ but not on $p_1$, and before it depended on $p_1$ but not on $p_n$. Thus, when the two utility functions are maximized subject to the (identical) budget constraints, the implications differ only in that 1 and $n$ are interchanged. Specifically, the demand for or supply of good 1 is homogeneous of degree 1 in $p_2, \ldots, p_n$, and $b_1$; all other demand and supply functions—including the one for money—are homogeneous of degree zero in the same variables.

This completes the first proof that, in the present context, money differs from commodities only because it serves as the numeraire, as unit of account. Were it not for its role of numeraire, money would be—in the present context again—an ordinary commodity.[1]

For the second proof, choose the guinea as numeraire (in principle, any nongood would do). It will be shown that all demand and supply functions are homogeneous of degree

[1] It is of interest to compare this conclusion with one of Robert Clower's. According to Clower, money would be an ordinary commodity if it were not for its role of medium of exchange. The other two functions of money —store of value, unit of account—do not, in Clower's opinion, make money essentially different from commodities.

zero, implying, in particular, that money ceases to be different from (other) commodities once it loses its role of numeraire. The economy is taken to have $n$ goods, the $n$th of which is money. It is again assumed that a good may be called money even if it does not serve as the unit of account. For the sake of notational convenience, $x_n$ and $b_n$ will continue to replace $m$ and $b$.

All $n$ goods have prices, in terms of guineas, and none of these prices is definitionally equal to 1. That is to say, every price is a variable. The utility function therefore becomes $u=f(x_1, \ldots, x_n; p_1, \ldots, p_n)$, a function containing as many quantities of goods as it contains prices. The budget constraint

$$\sum_{1}^{n} p_i(x_i - b_i) = 0$$

appears the same as before. There is a difference, however: this time, none of the prices needs to be unity.

The problem of maximizing $f(x_1, \ldots, x_n; p_1, \ldots, p_n)$ subject to

$$\sum_{1}^{n} p_i(x_i - b_i) = 0$$

is formally the same as that of maximizing $g(X_1, \ldots, X_n; P_1, \ldots, P_n)$ subject to

$$\sum_{1}^{n} P_i(X_i - B_i) = 0$$

considered in the preceding section. Consequently, (16) holds, *mutatis mutandis*.

If, for some $h_1(a)$ and $h_2(a)$, with $h_1(a) \neq 0$ when $a \neq 0$, one has grad $f(x_1, \ldots, x_n; ap_1, \ldots, ap_n) = h_1(a)$ grad $f(x_1, \ldots, x_n; p_1, \ldots, p_n) + h_2(a)\{p_1, \ldots, p_n\}$ for all $a \neq 0$, then $\bar{x}_i(ap_1, \ldots, ap_n) = \bar{x}_i(p_1, \ldots, p_n)$. The conclusion implies that the $\bar{x}_i$, and hence the demand and supply functions $\bar{x}_i - b_i$ are homogeneous of degree zero in $p_1, \ldots, p_n$. This completes the second proof that, in the present context, money differs from commodities only in that money serves as the numeraire.

Considering that in the second proof both the utility function and the budget constraint are symmetric with respect to all goods, the symmetry of the just-proved result is not surprising. Were there such a thing as a demand or supply function for guineas, asymmetry would immediately return; for that function would be homogeneous of degree one in its arguments.

For an application of the just-proved result, let the numeraire be a nongood, like the guinea, and let the utility function be specified as

$$u = f(x_1, \ldots, x_n)$$

This utility function—which contains money, through the presence of $x_n$—does not depend on prices. As a consequence, the by now familiar condition for homogeneous demand and supply functions is satisfied. (Formal confirmation is obtained by setting $h_1(a) \equiv 1$ and $h_2(a) \equiv 0$.) It follows that all demand and supply functions, including the one for money, are homogeneous of degree zero in $p_1, \ldots, p_n$. Naturally, for this conclusion to hold it is essential that utility be assigned to money, and that no utility be assigned to the numeraire.

## IV. Summary and Conclusion

Sections I and II are summarized in (16). Section III proved in two different ways that the Dusansky-Kalman model distinguishes money from commodities solely by giving money the role of numeraire. Put differently, it is money's function of unit of account that sets money and commodities apart, in the D-K model. Money's function of store of value is reflected in the appearance of money in the utility function; in this, however, money is indistinguishable from other goods. Money's function of medium of exchange is not reflected in the model, is not translated in mathematical terms; in this, then, money is also indistinguishable from other goods.

# The Foundations of Money Illusion in a Neoclassical Micro-Monetary Model: Reply

By Richard Dusansky and Peter J. Kalman*

Robert Clower and John Riley's (hereafter, C-R) "analysis" of money illusion rests entirely on the following claims:

1) That their equation (2) is "logically equivalent" to our (hereafter, D-K) sufficiency conditions presented in the 1974 issue of this *Review*.
2) That the assumption of degree zero homogeneity (in the variables $m$ and $p$) of the utility function "serves completely to characterize the class of illusion-free demand functions" derivable from ordinal utility theory.
3) That it is possible to reinstate the usual Slutsky properties by adopting the "semi-separable" utility function given in their equation (4).

We will show that each of these claims is false.

The first two claims can be analyzed jointly by employing a simple counterexample. Consider the following utility function:

$$u(x, m, p) = g(x, m, p) + h(p) \tag{1}$$

where $g(x, m, p)$ is any real valued twice continuously differentiable function, strictly quasi concave and increasing in $(x, m)$ and homogeneous (of any degree $k$) in $m$ and $p$, and where $h(p)$ is any real valued twice continuously differentiable *non*-homogeneous function of all prices. This utility function, $u(x, m, p)$, is *not* homogeneous in both $m$ and $p$; in particular, it is not homogeneous of degree $k$ and it is not homogeneous of degree zero. Thus, it does *not* satisfy either of the C-R conditions in 1) and 2) above. C-R's remarks would suggest, if they were true, that the demand functions derivable from (1) *must* exhibit money illusion. But such is not the case. The resulting demand functions are indeed free of money illusion. To see this, examine the first-order conditions for the maximization of (1) subject to the budget constraint:

$$(2)\quad \frac{\dfrac{\partial u(x, m, p)}{\partial x_i}}{\dfrac{\partial u(x, m, p)}{\partial x_j}} = \frac{\dfrac{\partial g(x, m, p)}{\partial x_i}}{\dfrac{\partial g(x, m, p)}{\partial x_j}} = \frac{p_i}{p_j}$$

$$i = 1, \ldots, j-1, j+1, \ldots, N-1$$

$$\frac{\dfrac{\partial u(x, m, p)}{\partial m}}{\dfrac{\partial u(x, m, p)}{\partial x_j}} = \frac{\dfrac{\partial g(x, m, p)}{\partial m}}{\dfrac{\partial g(x, m, p)}{\partial x_j}} = \frac{1}{p_j}$$

$$\sum_{i=1}^{N-1} p_i x_i + m = Y + L$$

If all money prices and initial balances were to increase by some $\alpha$ (this is the usual money-illusion experiment), these first-order conditions would yield the unique solution $(x, \alpha m)$. Hence *the commodity demand functions are free of money illusion.* (This should not be surprising. The homogeneity property of $g(x, m, p)$ implies that $\partial g(x, m, p)/\partial x_i$ is homogeneous of degree $k$ in $m$ and $p$, and that $\partial g(x, m, p)/\partial m$ is homogeneous of degree $k-1$ in $m$ and $p$, so that the D-K (1974, p. 118) conditions for the absence of money illusion are satisfied.)

The counterexample in (1) thus clearly demonstrates that C-R are wrong in both of their first two assertions. Since the utility function in (1) satisfies the D-K sufficiency conditions while violating C-R's equation (2), the alternative sufficiency condition in their (2) *cannot* be "logically equivalent"; although (2) is violated, it is still possible (given the D-K conditions are satisfied) to

* State University of New York at Stony Brook and Harvard University, respectively.

have homogeneous of degree zero commodity demand functions. Furthermore, since the utility function in (1) satisfies the D-K conditions while violating the zero-homogeneity of utility function assumption, the latter *cannot* possibly serve to "completely characterize the class of illusion-free demand functions." At best it is an overly restrictive sufficiency condition. *Under the D-K sufficiency conditions it is possible to have demand behavior which is free of money illusion without imposing the restriction that the utility function be homogeneous of any degree.*[1] Consequently, C-R's equations (2), (3), and their associated discussion—which focus on homogeneous utility functions—are *irrelevant* to the D-K paper.[2]

We now turn to the third C-R claim: that the semi-separable utility function in their equation (4)

$$f(x, m, p) = e(p)\cdot g(x, m) + h(p)$$

in general satisfies the sufficient conditions for the reinstatement of the standard Slutsky properties (i.e., symmetry and negative semi-definiteness of the Slutsky matrix). The easiest way to see that this claim is false is to examine the Slutsky system for the type of model under discussion. This system is:[3]

$$(3)\quad \frac{\partial x_i}{\partial p_k} + x_k\frac{\partial x_i}{\partial y} = \lambda\frac{D_{ki}}{D} - \sum_{j=1}^{n-1}\frac{\partial^2 f}{\partial x_j\partial p_k}\frac{D_{ji}}{D} - \frac{\partial^2 f}{\partial m\partial p_k}\frac{D_{ni}}{D} = S_{ik},\qquad i, k = 1, \ldots, n-1$$

where $D$ is the last bordered Hessian and $D_{ij}$ is the cofactor of element $i, j$ in the Jacobian (see our 1974 paper, p. 116). The expression for $S_{ki}$ is given by:

$$(4)\quad \frac{\partial x_k}{\partial p_i} + x_i\frac{\partial x_k}{\partial y} = \frac{\lambda D_{ik}}{D} - \sum_{j=1}^{n-1}\frac{\partial^2 f}{\partial x_j\partial p_i}\frac{D_{jk}}{D} - \frac{\partial^2 f}{\partial m\partial p_i}\frac{D_{nk}}{D} = S_{ki},\qquad i, k = 1, \ldots, n-1$$

In order to have $S_{ik}=S_{ki}$, it is sufficient to establish the equality of the right-hand sides of (3) and (4). To do this, examine the C-R semi-separable utility function and compute the relevant second partial derivatives:

$$\frac{\partial^2 f}{\partial x_j\partial p_k} = \frac{\partial g(x, m)}{\partial x_j}\cdot\frac{\partial e(p)}{\partial p_k}$$

$$\frac{\partial^2 f}{\partial x_j\partial p_i} = \frac{\partial g(x, m)}{\partial x_j}\cdot\frac{\partial e(p)}{\partial p_i}$$

$$\frac{\partial^2 f}{\partial m\partial p_k} = \frac{\partial g(x, m)}{\partial m}\cdot\frac{\partial e(p)}{\partial p_k}$$

$$\frac{\partial^2 f}{\partial m\partial p_i} = \frac{\partial g(x, m)}{\partial m}\cdot\frac{\partial e(p)}{\partial p_i}$$

It is obvious that in general

$$\frac{\partial^2 f}{\partial x_j\partial p_k} \neq \frac{\partial^2 f}{\partial x_j\partial p_i},\qquad \frac{\partial^2 f}{\partial m\partial p_k} \neq \frac{\partial^2 f}{\partial m\partial p_i}$$

and that these second partial derivatives do not vanish. Similarly, in general $D_{ji}\neq D_{jk}$ and $D_{ni}\neq D_{nk}$. Hence the symmetry property is in general *not* reinstated.

The error in the C-R analysis of the symmetry property emanates from the process of pulling functional forms out of the air. This can be avoided by taking care to *derive* classes of functions which satisfy a specified separability condition, instead of guessing at functions that "might work." For the problem at hand, we now show how a general separable class of utility functions yielding the Slutsky properties can be derived.

We begin by introducing some convenient notation. Let the utility function $f(x, m, p)$ be denoted by $f(q, a)$ where $q=(x, m)$ and $a=(p, 1)$, let the constraint $y+L=\sum_1^{n-1} p_i x_i + m$ be denoted by $g(q, b)$ where $b=(a, L, y)$. The element in the $i$th row and $h$th column of the Slutsky matrix (see the authors, 1973, equations (31) and (32)) is:[4]

[1] Operationally this means that there is a larger admissible class of utility functions which is consistent with demand behavior free of money illusion.

[2] Similarly, the reservations expressed in C-R's fn. 5 do not apply to our paper. They apply only to C-R, who choose to focus on homogeneous utility functions.

[3] See the authors (1972), pp. 343–46 for derivation.

[4] Where $D_{hi}$ is the cofactor of the element in the $h$th row and the $i$th column of the Jacobian of the first-order conditions and $D$ is the determinant of the Jacobian.

$$S_{ih} = \lambda \frac{D_{hi}}{D} - \sum_{j=1}^{n} f_{q_j a_h} \frac{D_{ji}}{D}$$

or in matrix notation

$$(5) \qquad S = \frac{1}{D} [\lambda\Delta + F\Delta]$$

where
$$F = \nabla_q \nabla_a f$$
$$(\Delta)_{ji} = D_{ji}$$

So $S = S'$ if $F\Delta = \Delta F$. However, $F\Delta = \Delta F$ if

$$(6) \qquad F = I\phi(q, a)$$

where $I$ is the identity matrix. Hence we now need to construct a general solution to the system of partial differential equations stated in (6). By doing this, we obtain a general class of utility functions which yield symmetry of the Slutsky matrix. Rewrite (6) as

$$(7) \quad \frac{\partial^2 f}{\partial a_i \partial q_j} = \delta_{ij}\phi(q, a), \qquad i, j = 1, \ldots, n,$$

where $\delta_{ij} = \begin{cases} 1, & \text{if } i = j \\ 0, & \text{otherwise} \end{cases}$

Integrating with respect to $a_i$ we get

$$\frac{\partial f}{\partial q_j} = \mu(q, a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_n)$$

$\forall i \neq j$, ($i$ taken one at a time, $i \in \{1, \ldots, n\}$). Hence we have

$$(8) \qquad \frac{\partial f}{\partial q_j} = \sigma(q, a_j)$$

Now taking partials of (8) with respect to $a_j$ we get

$$\frac{\partial^2 f}{\partial q_j \partial a_j} = \frac{\partial \sigma}{\partial a_j} = \beta(q, a_j)$$

$\forall j \in \{1, \ldots, n\}$. But by (7) $\beta \equiv \phi(q, a)\ \forall j$. Hence $\beta$ is independent of $j$. So we have

$$(9) \qquad \phi(q, a) = \phi(q)$$

Similarly for $q_j$ we get

$$(10) \qquad \phi(q, a) = \phi(a)$$

Hence from (9) and (10) we have $\phi(q, a) = K$ ($K$ is constant independent of $q$ and $a$). So in view of this, (7) becomes

$$(11) \qquad \frac{\partial^2 f}{\partial q_j \partial a_i} = \delta_{ij} K$$

Now for the case $i = j$ we have

$$\frac{\partial f}{\partial a_i} = Kq_i + k(q_1, \ldots, q_{i-1}, q_{i+1}, \ldots, q_n, a)$$

For the case $i \neq j$ we have (by (11))

$$\frac{\partial^2 f}{\partial q_j \partial a_i} = \frac{\partial k}{\partial q_j} = 0 \qquad \forall j \neq i$$

Hence $k = k(a)$. So we have

$$\frac{\partial f}{\partial a_i} = Kq_i + k(a)$$

Integrating with respect to $a_i$ we have

$$f = Ka_i q_i + \sigma(a) + \gamma(q, a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_n)$$

Reversing the order of integration we obtain in a similar way

$$f = Ka_i q_i + \pi(q) + \rho(q_1, \ldots, q_{i-1}, q_{i+1}, \ldots, q_n, a)$$

Combining we obtain

$$f = Ka_i q_i + \pi(q) + \sigma(a) + \alpha(q_1, \ldots, q_{i-1}, q_{i+1}, \ldots, q_n, a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_n) \qquad \forall i \in \{1, \ldots, n\}$$

Recalling (11), however, the most general form that

$$\alpha(q_1, \ldots, q_{i-1}, q_{i+1}, \ldots, q_n, a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_n)$$

can take on is

$$\alpha = K \sum_{j=1}^{n} a_j q_j - Ka_i q_i$$

Thus we obtain the general solution to (7).

This is

$$(12)\quad f(q, a) = K \sum_{j=1}^{n} a_j q_j + \pi(q) + \sigma(a)$$

which is a general class of utility functions consistent with reinstatement of the symmetry property of the Slutsky system.[5]

[5] It can easily be shown that this utility function yields the negative semidefiniteness Slutsky property if $(K+\lambda)\geq 0$.

# Faculty Salaries: Is There Discrimination by Sex, Race, and Discipline? Additional Evidence

By Emily P. Hoffman*

In a recent paper in this *Review*, Nancy Gordon, Thomas Morton, and Ina Braden (G-M-B) presented a model of faculty salary determination and results of an empirical test of their model. In this paper I present results of a replication of their study using data from another institution and results from tests of alternative models.

Faculty salary differentials can be explained in part by differences in individuals' characteristics. Jacob Mincer has stated that differences among individuals in their stock of human capital (for example, level of education, years of work experience) explains much of the variation in their earnings. College and university administrators claim that faculty salary depends on productivity in the areas of teaching, scholarship, and service. Differences in demand conditions among disciplines suggest including department or school among the factors thought to determine faculty salaries.[1]

There is no consensus among economists on a definition of labor market discrimination. G-M-B have an implicit definition of discrimination contained in their model. Their definition of labor market discrimination is that the sex differential in salary which is unexplained by differences in individual characteristics of age, seniority, education, rank, race, and discipline is due to sex discrimination. I propose a different definition of discrimination in that I omit rank as one of the relevant characteristics. Sex discrimination may occur through slower promotion rates for females than for males, in which case rank itself would reflect discrimination.[2]

I had access to a set of data from another institution, comparable to the G-M-B data. The two institutions are both large Ph.D. granting universities with similar faculty size. The variables in both studies are the same.

In Table 1, empirical results of a test of the G-M-B Model I using the new data set are presented alongside the G-M-B empirical results. Model I is as follows:

$$(1) \quad Ln\ W_i = a_0 + f(A_i) + a_5 L_i + d^n(E_i) + d^m(J_i) + d^q(S_i) + d^r(R_i) + d^t(D_i) + e_i$$

where, for the $i$th employee, $W_i$ represents salary, $A_i$ is age, $L_i$ is time at the university (seniority), $E_i$ is education, $J_i$ is academic rank, $S_i$ is sex, $R_i$ is race, $D_i$ is department, and $e_i$ is the disturbance term.[3] Only the coefficients for sex, race, seniority, and discipline are presented here.

There are few differences in results between the two sets of data. G-M-B find that women earn 9.5 percent less than men, while

* Assistant professor of economics, University of Missouri-Rolla. This paper was written while I was a doctoral candidate, University of Massachusetts. I wish to thank Ronald Ehrenberg and Ronald Oaxaca for their helpful suggestions and encouragement, and Richard Hoffman for his valuable computer programming assistance. Support by doctoral dissertation grant #DL 91-25-74-27 from the U.S. Department of Labor, Manpower Administration, Manpower Development Training Act is gratefully acknowledged.

[1] Another approach, used by Barbara Reagan and Betty Maynard, is to group departments by entrance salary levels. Their justification for this is that academic labor markets operate as internal labor markets; supply and demand forces are felt primarily at the entry level and have little effect on senior level faculty salaries. The internal labor market concept was developed by Peter Doeringer and Michael Piore.

[2] Janice Madden defines three types of sex discrimination: wage discrimination occurs when wage differentials are not based on productivity differences; occupational discrimination occurs when the number of females employed in each occupation is not based on productivity differences; cumulative discrimination occurs when a factor has low productivity due to past discrimination, so that the individual's characteristics incorporate discrimination. In this paper I demonstrate only the existence of wage discrimination.

[3] This is the notation of the G-M-B article, to which the reader is referred for a more complete explanation.

Table 1—Comparison of Selected Estimated Regression Coefficients of the G-M-B Model for G-M-B and Hoffman Data

| G-M-B Data | $\beta$ | $t$-value | Hoffman Data | $\beta$ | $t$-value |
|---|---|---|---|---|---|
| Sex, Female=1 | −.095 | 7.0 | Sex, Female=1 | −.074 | 7.1 |
| Race, Black=1 | .127 | 5.5 | Race, Black=1 | .074 | 4.1 |
| Seniority | −.005 | 5.4 | Seniority | −.002 | 2.5 |
| Discipline | | | Discipline | | |
| Fine Arts | .002 | 0.1 | Arts & Humanities | −.071 | 5.0 |
| Social Science | .096 | 4.3 | Social & Behavioral Science | −.036 | 2.3 |
| Quantitative Social Science | .186 | 7.5 | Natural Science & Math | −.026 | 1.7 |
| Engineering & Science | .139 | 7.3 | Engineering | .039 | 2.1 |
| Health | .188 | 9.7 | Public Health | −.051 | 2.2 |
| Law | .159 | 2.2 | Business Administration | .039 | 2.0 |
| Medicine | .402 | 16.2 | Physical Education | −.078 | 3.5 |
| Education | .189 | 9.0 | Graduate School Programs | −.002 | 0.1 |
| Other | Reference Group | | Natural Resources | −.062 | 3.7 |
| | | | Other | −.030 | 0.6 |
| | | | Education | Reference Group | |
| $\bar{R}^2$ | .794 | | $\bar{R}^2$ | .799 | |

I find sex causes a 7.4 percent difference in salary. Blacks earn significantly more than whites, which is probably due to a limited supply of blacks relative to an increased demand, as the administration attempted to comply with Affirmative Action legislation.

Model I was then tested with the rank variables omitted, using my data for males and females combined, and for each sex separately (with the sex variable omitted).[4] With this alternative definition of discrimination, the coefficient on sex more than doubles, from −.074 to −.162 ($t$=10.5).[5] The $R^2$ was .547 for the regression for males and females combined. For the female sample, age and seniority variables are more significant when rank is omitted. For both the male sample and the all faculty sample, the coefficient for seniority is no longer significant once rank is omitted. Negative coefficients for age beyond age 35 suggests young faculty members' salaries rise faster than those of older faculty, which is consistent with the internal labor market concept. At this university, there was a large increase in demand for faculty over the last decade, which had a greater effect on entry level faculty salaries than on those of senior faculty.

The age, seniority, and degree variables were then replaced by the following two variables: 1) the quadratic form of years of potential experience measured as years since highest degree, which is an estimate of years of professional experience; and 2) years of schooling since high school. It was then possible to estimate the coefficients of the human capital postschooling investment model.

The human capital postschooling investment model performs well in predicting faculty salaries.[6] The $R^2$ was .595 for the regression fitted for males and females combined. The estimated coefficients can be interpreted as follows: each year of experience increases one's salary at most 4.3 percent per year, with diminishing returns occurring; and each

[4] In each case when male and female models were separately fitted, the estimated coefficients in each model were found to differ significantly.

[5] In a study of salary differentials of professional employees of a firm, Burton Malkiel and Judith Malkiel found that discrimination against females occurred through lower job level assignments to females than to males with the same characteristics. They measured discrimination both with and without job level as an explanatory variable, and found greater discrimination when job level was omitted.

[6] Using 1970 National Science Foundation Register data for Ph.D.s and the human capital approach, George Johnson and Frank Stafford found that female faculty earn less than male faculty. They attribute part of the male-female salary differential to discrimination, and part to differences between males and females in human capital investments, i.e., less labor force participation and less on-the-job training for females.

year of schooling after high school increases one's salary an average of 7.6 percent.[7] In this model, females earn 14.1 percent less than males ($t=9.8$).

One can compare the amount of discrimination measured as a residual predicted by each model under two alternative assumptions.[8] Under Assumption 1, I predict what the average male and female salaries would be if both were compensated by the male salary structure, while Assumption 2 is that males and females would be compensated by the female salary structure. Any resulting difference in male and female average salaries which is not explained by differences in average characteristics, when the same salary structure is used for both groups, is attributed to discrimination. The G-M-B model attributes between 29 and 35 percent of the salary differential by sex to discrimination, based on Assumptions 1 and 2, respectively. Omitting rank from their model and using my data, from 56 to 68 percent of the salary differential by sex is seen to be due to discrimination, based on Assumptions 1 and 2, respectively (for males and females with equal characteristics). Again we observe that omitting rank as an explanatory variable increases the measured amount of discrimination, almost doubling it.

The Gordon-Morton-Braden model gives an estimate of sex discrimination which is only half that given by my alternative model, which accounts for the possibility that discrimination against female faculty may occur through slower promotion rates. The human capital model is shown to perform well in explaining faculty salaries.

[7] This interpretation is subject to Sherwin Rosen's caveat concerning the difficulty of identifying rate of return to schooling from a reduced form equation.

[8] This technique of measuring discrimination was developed by Ronald Oaxaca.

# Default Risk, Homemade Leverage, and the Modigliani-Miller Theorem: Note

*By* KÅRE P. HAGEN*

In the March 1974 issue of this *Review* David Baron uses a stochastic dominance argument in an attempt to prove that the Modigliani-Miller (M-M) theorem is generally valid even in case of default risk. For this purpose he uses the familiar two-firm paradigm where both firms have identical probability distributions for gross returns, and one firm has some debt in its capital structure whereas the other firm is financed entirely by equity capital. If all equity investors in the levered firm also hold bonds in that firm or if all investors can borrow at the same nominal interest rate as firms, then he shows that in equilibrium both firms must have the same total market value.

Although there is nothing formally wrong in his arguments, Baron does not prove what he sets out to prove. What he proves seems to be the (fairly obvious) fact that at an equilibrium in a perfect capital market two firms with identical probability distributions for gross returns must have the same total market value. This does not imply, however, that the equilibrium value of a firm is independent of its capital structure. In fact, the common market value of the two firms will in general be dependent on the debt-equity ratio in the levered firm. To show this a simple counterexample will suffice.

## I

The conventional one-period model where investors invest at the beginning of the period while returns materialize at the end is used with the following notations:

- $X_j(\theta)$ = gross returns in firm $j$ if state of the world $\theta$ obtains, $\theta \in \Omega$, where $\Omega$ is the state space
- $R_j(\theta)$ = returns to equity in firm $j$ in state $\theta$
- $B_j(\theta)$ = returns to bondholders in firm $j$ in state $\theta$
- $D_j$ = total debt liability in firm $j$ (principal plus interest payments due at the end of the period)
- $\alpha_{ij}$ = the fraction investor $i$ holds of the shares of firm $j$
- $\beta_{ij}$ = the fraction investor $i$ holds of the bonds issued by firm $j$
- $S_j$ = market value of firm $j$'s equity
- $B_j$ = market value of firm $j$'s bonds
- $V_j \equiv S_j + B_j$ = total market value of firm $j$
- $Y_i(\theta)$ = investor $i$'s final wealth in state $\theta$
- $W_i$ = investor $i$'s initial wealth
- $\pi_i(\theta)$ = investor $i$'s probability assessments
- $U_i(Y_i(\theta))$ = investor $i$'s utility function (strictly concave)

Clearly,

$$R_j(\theta) = \text{Max}\,[0,\, X_j(\theta) - D_j]$$
$$B_j(\theta) = \text{Min}\,[D_j,\, X_j(\theta)]$$
$$\text{and } X_j(\theta) = R_j(\theta) + B_j(\theta) \qquad \text{for all } \theta \in \Omega$$

Two firms with identical gross return patterns over states of the world are assumed, i.e., $X(\theta) = X_j(\theta)$ for all $\theta \in \Omega$, $j = 1, 2$. Firm 1 is financed entirely by equity capital such that $V_1 \equiv S_1$, while the total debt liability in firm 2 is $D_2$. Short selling of stocks and bonds is generally possible. If $\beta_{ij} < 0$, investor $i$ is issuing bonds with the same return characteristics as those issued by firm $j$. Moreover, riskless lending and borrowing are available to the investors at a zero interest rate. Each investor owns initially a fraction $\delta_i$ of each firm and investors are assumed to rank portfolios according to expected utility of final wealth.

$$\text{Define } \hat{\Omega}(D_2) \equiv \{\theta \in \Omega \mid X(\theta) \geqq D_2\}$$
$$\text{and } \bar{\Omega}(D_2) \equiv \Omega \backslash \hat{\Omega}(D_2)$$

* Assistant professor of economics, The Norwegian School of Economics and Business Administration.

i.e., $\bar{\Omega}(D_2)$ are the states of the world in which firm 2 goes bankrupt.

Using the budget constraint, final wealth can be written as (1a) if $\theta \in \hat{\Omega}$ or (1b) if $\theta \in \bar{\Omega}$.

$$\text{(1a)} \quad Y_i(\theta) = W_i + \alpha_{i1}(X(\theta) - V_1) + \alpha_{i2}(X(\theta) - S_2) - \beta_{i2}B_2 + (\beta_{i2} - \alpha_{i2})D_2$$

$$\text{(1b)} \quad Y_i(\theta) = W_i + \alpha_{i1}(X(\theta) - V_1) + \beta_{i2}(X(\theta) - B_2) - \alpha_{i2}S_2$$

where $W_i = \delta_i(V_1 + V_2)$.

The first-order conditions for optimal portfolios for all $i$ can be written as:

$$\text{(2)} \qquad V_1 = \sum_{\theta \in \Omega} \omega_i(\theta) X(\theta)$$

$$\text{(3)} \qquad S_2 = \sum_{\theta \in \hat{\Omega}(D_2)} \omega_i(\theta)(X(\theta) - D_2)$$

$$\text{(4)} \qquad B_2 = \sum_{\theta \in \hat{\Omega}(D_2)} \omega_i(\theta) D_2 + \sum_{\theta \in \bar{\Omega}(D_2)} \omega_i(\theta) X(\theta)$$

$$\text{where } \omega_i(\theta) \equiv \frac{\pi_i(\theta) U_i'(Y_i(\theta))}{\sum_{\theta \in \Omega} \pi_i(\theta) U_i'(Y_i(\theta))}$$

The conditions (2), (3), and (4) together with the market-clearing conditions $\Sigma_i \alpha_{ij} = 1$, $\Sigma_i \beta_{ij} = 1$ for all $j$, characterize an equilibrium in the capital market.

The term $\omega_i(\theta)$ is investor $i$'s marginal rate of substitution between a unit return in state $\theta$ and a unit of riskless return. Hence, $\omega_i(\theta)$ can be interpreted as the implicit price in terms of the riskless asset investor $i$ is willing to pay for a claim to a unit return contingent on state $\theta$. As the price of a unit of riskless return is $\Sigma_{\theta \in \Omega}\, \omega_i(\theta) = 1$, the riskless asset is a numeraire.

As can be seen from (2), (3), and (4), $V_2 \equiv S_2 + B_2 = V_1$ so that the two firms will in equilibrium always have the same market value. But this common market value will in general depend on the debt level in the levered firm unless $\omega_i(\theta)$ is independent of $D_2$ for all $\theta$ and for all $i$. Hence we have the immediate result that the market value of the two firms is independent of the leverage in the levered firm if and only if $\omega_i(\theta)$ does not depend on $D_2$ for all $\theta$ and for all $i$.

If the market structure were complete, i.e., there are as many securities with linearly independent return patterns as states of the world, the return pattern on the optimal portfolios would be independent of the return structure of the individual securities in which case $\omega_i(\theta)$ would clearly be independent of $D_2$. Moreover, irrespective of the completeness of the market structure, if $\bar{\Omega}(D_2) = \phi$ for any relevant $D_2$ (no default risk), then $B_2 = D_2$ from (4) so that $D_2$ drops out of (1) which again would imply $\omega_i(\theta)$ to be independent of $D_2$.

In general, with incomplete markets and default risk in the levered firm, $\omega_i(\theta)$ will be independent of $D_2$ if and only if $\beta_{i2} = \alpha_{i2}$ for all $i$ as can be seen from (1). Hence, in an economy with incomplete markets for risk, a sufficient condition for firm values to be dependent on leverage is a nonzero default risk and that investors in equilibrium hold different fractions of the equity and bonds of the levered firm ($\alpha_{i2} \neq \beta_{i2}$).

## II

A numerical example may be in order to illustrate the above point. Assume two investors each of whom owns initially 50 percent of each firm, i.e., $W_1 = W_2 = 0.5V_1 + 0.5V_2$. The utility functions are assumed to be given by $U_1(Y_1) = Y_1 - Y_1^2/730$ and $U_2(Y_2) = Y_2 - Y_2^2/870$. First it is assumed that both firms are financed entirely by equity capital so that $V_j \equiv S_j$, $j = 1, 2$. Riskless lending and borrowing at a zero interest rate are available for both investors. There are three different states of the world labelled 1, 2, and 3. It is postulated that the following data are given:

| $\theta$ | 1 | 2 | 3 |
|---|---|---|---|
| $X_1(\theta) = X_2(\theta)$ | 150 | 200 | 300 |
| $\pi_1(\theta)$ | 1/2 | 1/4 | 1/4 |
| $\pi_2(\theta)$ | 1/4 | 1/4 | 1/2 |

It is fairly easy to verify that the equilibrium solution is given by $\alpha_{11} = \alpha_{12} = 1/3$, $\alpha_{21} = \alpha_{22} = 2/3$, $V_1 = V_2 = 193.8$.

The above example is now modified such that the firm labelled 2 is financed both by equity and debt. In all other respects the relevant data are the same as above. It is

assumed that $D_2=160$. Clearly $D_2/B_2$ will be the gross nominal interest rate on firm 2's bonds. Investors are assumed to be able to issue bonds on the same terms as firms. That means that investors can issue bonds with the same return characteristics as those of firm 2 at the same nominal interest rate. A personal bond issue takes place if $\beta_{i2}<0$. Moreover, riskless lending and borrowing at a zero interest rate are still available.

The total returns to shareholders and bondholders of the two firms will now be as follows:

| $\theta$ | 1 | 2 | 3 |
|---|---|---|---|
| $X_1(\theta)=R_1(\theta)$ | 150 | 200 | 300 |
| $R_2(\theta)$ | 0 | 40 | 140 |
| $B_2(\theta)$ | 150 | 160 | 160 |
| $X_2(\theta)$ | 150 | 200 | 300 |

As can be seen from the table, firm 2 goes bankrupt in state 1 so that there is a positive probability for bankruptcy for both investors. It is assumed again that each investor holds initially 50 percent of each firm, that is, 50 percent of the shares of firm 1 and 50 percent of the shares and bonds of firm 2.

After some tedious calculations, it is found that an equilibrium is characterized by

$$\begin{aligned}
V_1 &\equiv S_1 = 195 \\
S_2 &= 40 \\
B_2 &= 155 \\
V_2 &\equiv S_2 + B_2 = 195 \\
\alpha_{11} &= -6 - \beta_{12} \\
\alpha_{12} &= (20 + 3\beta_{12})/3 \\
\beta_{12} &= \text{arbitrary} \\
\alpha_{21} &= 7 + \beta_{12} \\
\alpha_{22} &= -(17 + 3\beta_{12})/3 \\
\beta_{22} &= 1 - \beta_{12}
\end{aligned}$$

As can be seen, the optimal portfolios are not unique. This is due to the fact that there are four securities with different return patterns (including the riskless opportunity) and just three states of the world. Only three of these return patterns are linearly independent. Hence, the investors can obtain their most preferred pattern of final wealth over states of the world by combining these four securities in an infinite number of ways. Note, however, that for any choice of $\beta_{12}$, $\alpha_{i2}\neq\beta_{i2}$, $i=1, 2$. For example, for $\beta_{12}=-6$, the solution is:

$$\begin{aligned}
\alpha_{11} &= 0 & \alpha_{21} &= 1 \\
\alpha_{12} &= 2/3 & \alpha_{22} &= 1/3 \\
\beta_{12} &= -6 & \beta_{22} &= 7
\end{aligned}$$

The nominal interest rate on risky bonds, $(D_2/B_2-1)100$, is 100/31 percent. Investor 1 issues six times the amount of risky bonds issued by firm 2 with the same return characteristics at the same nominal interest rate. The individual transactions corresponding to the above portfolios are summarized below:

| | Shareholdings Firm 1 | Shareholdings Firm 2 | Borrowing (−)/ Lending (+) Riskless | Borrowing (−)/ Lending (+) Risky |
|---|---|---|---|---|
| Investor 1 | 0 | 80/3 | 3295/3 | −930 |
| Investor 2 | 195 | 40/3 | −3295/3 | 1085 |
| Total | 195 | 40 | 0 | 155 |

The notable point in the above example is that although $V_1=V_2=195$, this common value is different from the case where both firms were financed by equity capital only.[1]

## III

Consider in general a one-period exchange economy with $s$ states of the world and $n$ firms with gross returns denoted by $X_j(\theta)$, $\theta\in\Omega$. Investor $i$'s income pattern over states of the world at the end of the period is given by

$$Y_i(\theta) = \sum_{j=1}^{n} \alpha_{ij}R_j(\theta) + \sum_{j=1}^{n} \beta_{ij}B_j(\theta) + rm_i, \quad \theta\in\Omega \tag{5}$$

where $m_i$ denotes riskless lending or borrowing and $r$ is one plus the riskless rate of interest. If $\beta_{ij}<0$, investor $i$ is issuing risky bonds

[1] In fact, if the levered firm in the above example borrows at least as much as to make the default risk positive, the values of the two firms will be independent of the particular debt level in the levered firm because we then have as many linearly independent securities as states of the world (complete markets).

with the same return characteristics as those issued by firm $j$. An investor's income pattern over states of the world can be represented by an $s$-component vector and it is assumed that each investor has a unique preference ordering over such income vectors. A feasible income pattern obtainable in the security markets is given by (5). The set of all obtainable income vectors will be called the feasible income space, the structure of which will depend on the generating return vectors $R_j(\theta)$ and $B_j(\theta)$ which in turn depend on the capital structures in the various firms. Let $\hat{Y}_i(\theta)$ denote the return pattern on investor $i$'s optimal portfolio in some feasible income space corresponding to some set of capital structures in the various firms. It is fairly obvious that firm $k$'s equilibrium value will be independent of its capital structure if and only if the income patterns $\hat{Y}_i(\theta)$ remain optimal for all $i$ in any feasible income space corresponding to any set of financial arrangements in firm $k$.[2] This holds if and only if at least one of the following two conditions is satisfied:[3]

(i) The feasible income space must remain unchanged for different debt-equity ratios in firm $k$.

(ii) The return patterns on the equilibrium portfolios corresponding to all the feasible income spaces which can be generated by varying the debt-equity ratio in firm $k$ must be contained in the intersection of all the feasible income spaces so created.

Condition (i) is always satisfied if there is no default risk in firm $k$ for all relevant debt levels (the original M-M theorem). If there is default risk in firm $k$, condition (i) holds if:

(ia) There are as many securities with linearly independent return patterns as there are states of the world. In that case the return vectors span the whole $s$-dimensional income space so that the income patterns $\hat{Y}_i(\theta)$ will remain optimal for any particular capital structure in firm $k$.

(ib) The return patterns $R_k(\theta)$ and $B_k(\theta)$ of firm $k$ are linearly dependent on the rest of the market for any debt level in firm $k$.

A special case of (ib) would be if any return pattern $B_k(\theta)$ which the firm can create could have been created by an investor.[4] He can do that by a limited liability arrangement where he buys equal shares of total stocks and bonds of firm $k$ and finances a varying part of these purchases by a personal loan pledging his shares and bonds in firm $k$ as the sole collateral. If the returns on his shares and bonds in firm $k$ are insufficient to meet the nominal payments due on the loan, the lenders get the returns on the pledged securities and the investor pays nothing but forfeits his securities in firm $k$. By varying the margin, i.e., his homemade leverage, the investor can replicate the return pattern on any conceivable bond issue in firm $k$.

If condition (i) does not hold, the firm will in fact create a new security with a unique return pattern by changing its capital structure. In that case condition (ii) must hold if the firm's value is to remain unchanged with different debt levels. It is easy to see that the intersection of the feasible income spaces so created is given by vectors of the form

$$Y_i(\theta) = rm_i + \sum_{j\neq k} \alpha_{ij}R_j(\theta) + \sum_{j\neq k} \beta_{ij}B_j(\theta) + \gamma_{ik}X_k(\theta)$$

That is, for any debt level in firm $k$ it must be optimal for each investor to hold the same fraction of firm $k$'s equity and bonds ($\alpha_{ik} = \beta_{ik} \equiv \gamma_{ik}$ for all $i$). For the M-M theorem to

[2] Sufficiency follows from the fact that if $\hat{Y}_i(\theta)$ are invariant to the capital structure in firm $k$, implicit prices $\omega_i(\theta)$ will be independent of the capital structure in that firm. If the value of firm $k$ shall remain the same for any capital structure in that firm, it is clearly also necessary.

[3] Condition (i) is obvious. Even though condition (i) does not hold, condition (ii) guarantees that the return patterns on the optimal portfolios corresponding to the various feasible income spaces must remain the same because they are obtainable in each of the incomes spaces so created. For example, let $\bar{S}$ and $\hat{S}$ be two feasible income spaces corresponding to two different debt levels in firm $k$ and let $\bar{Y}_i(\theta)$ and $\hat{Y}_i(\theta)$ be the return patterns on the optimal portfolios corresponding to these two situations. Since $\bar{Y}_i(\theta)\in\bar{S}\cap\hat{S}$ and $\hat{Y}_i(\theta)\in\bar{S}\cap\hat{S}$, we must have that $\hat{Y}_i(\theta)=\bar{Y}_i(\theta)$ for all $i$, provided that the optimal return patterns are unique which will always be the case with strictly concave utility functions.

[4] This is equivalent to Joseph Stiglitz's assumption, p. 788.

be globally true, i.e., to be valid for all $j$, the return patterns on the equilibrium portfolios satisfying condition (ii) must be of the form

$$Y_i(\theta) = rm_i + \sum_j \gamma_{ij} X_j(\theta)$$

where $\gamma_{ij}$ is the optimal fraction investor $i$ holds of the total stocks and bonds of firm $j$. That is, each investor must in equilibrium hold the same fraction of the total amount of shares and risky bonds issued by any firm. If investors are ranking portfolios according to expected utility, it is well known[5] that each investor will in equilibrium hold the same share of *all* the risky securities if and only if separation obtains in the individual portfolios and investors have the same expectations. That is, the return patterns on the equilibrium portfolios will be of the form $Y_i(\theta)=rm_i+\gamma_i\sum_j X_j(\theta)$ for all $i$. Hence, portfolio separation and homogeneous beliefs are clearly sufficient conditions for the M-M theorem to be valid in case of default risk.

## IV

Let us now reexamine Baron's proof of the M-M theorem under default risk in the light of the above arguments. It is not sufficient for the theorem to be valid that all equity investors in the levered firm also hold bonds in that firm, unless it would be optimal for each investor to hold the same fraction of the equity and bonds in that firm (condition (ii)). Whether his second assumption is sufficient depends on how one understands the assumption that investors are able to borrow at the same nominal interest rates as firms. On page 178 it seems that he means that an investor can replicate on his personal loan the same return pattern as on the bonds issued by the levered firm such that lenders would be indifferent between lending to the investor and buying the risky bonds, i.e., allowing $\beta_{ij}$ to be negative. This is, however, not sufficient for the theorem to be valid. The investors must be able to create any conceivable return pattern which the firm could have created itself by issuing different amounts of risky bonds, and for the lenders it must be immaterial whether these return patterns are created by individuals or by firms. By changing its capital structure the firm would in this case create an investment opportunity which is already available in the market and hence the feasible income space and firms' market values would remain unchanged. Regardless of the capital structure in firm $k$, the income patterns $\hat{Y}_i(\theta)$ will in this case remain optimal and can be obtained by buying shares and bonds in firm $k$ on margin and pledging these securities as the sole collateral. Hence, investors can undo the allocation effects from changing the debt-equity ratio in firm $k$ by a suitable adjustment of the homemade leverages on their personal loans. Those homemade leverages may, however, not coincide with the observed leverage in firm $k$.

If the above conditions are not satisfied, firms' equilibrium values will depend on their capital structures. It will, however, always be true that firms with identical gross returns have the same total market value. But this does not prove that the market values are independent of the way firms are financed.

[5] See David Cass and Stiglitz for a rigorous discussion of portfolio separation.

# Default Risk and the Modigliani-Miller Theorem: A Synthesis

*By* DAVID P. BARON*

Several recent studies have extended the original results of Franco Modigliani and Merton Miller (M-M) to the case in which there is default risk on the debt obligations of a firm. These extensions are concerned with the relative values of firms in a risk class, with the absolute value of those firms, and with the preferences of investors for changes in capital structure. I have given conditions under which the relative values of firms in the same risk class are independent of the capital structure of any firm in that class, but this does not imply that the common value of those firms in the risk class will in general be independent of the capital structure as indicated by Joseph Stiglitz (Section III) and Kåre Hagen. If investors may create any return opportunities that a firm is able to create by altering its capital structure, the value of the firm will, however, be independent of its capital structure. For example, investors will be able to create the equivalent return opportunities by borrowing on personal account and pledging shares of an unlevered firm as collateral, since the investor can then borrow under the same conditions and at the same nominal interest rate as can the firm as indicated in my earlier paper. These results pertain to firm valuation, but investors are interested in the return on their portfolio and not directly in the value of firms. Vernon Smith has investigated the preferences of investors for the debt-equity ratio of a variable-scale firm and has indicated that investors are not indifferent to changes in that ratio and that investors may not prefer a change in the debt-equity ratio of a firm even if the value of the firm is increased by that change.[1]

In order to place these results in perspective, it is useful to return to the original M-M theorem that was given for firms with a fixed scale of investment. That theorem actually has three facets that may be stated as follows:

*I:* In the absence of default risk the values of all firms in the same risk class are equal regardless of their capital structures.[2]

*II:* In the absence of default risk the common value of firms in a risk class is independent of the capital structure of any firm.[3]

*III:* In the absence of default risk investor preferences are in agreement with changes in the value of firms in the sense that investors will prefer a change

* Professor of managerial economics and decision sciences, Graduate School of Management, Northwestern University. I wish to thank Mark Satterthwaite and Robert Taggart for their comments on an earlier version of this paper.

[1] As will be indicated below the differences among these results stem from differing assumptions made regarding the completeness of the market in which the firms' securities are traded. If investors may borrow on personal account and create the same return opportunities as firms create by altering their capital structure, the common value of the firms in a risk class will be independent of capital structure, and investors will be indifferent to changes in the capital structure. In my earlier paper, I gave a homemade leverage argument that implies that the capital market is complete in this sense. Without these homemade leverage opportunities or an equivalent completeness condition, the values of firms in a risk class and investor preferences will depend on a firm's financial structure.

[2] The proof of M-M's Proposition I is a proof of the first facet. In the introduction to their Proposition I, M-M state that they will "exhibit the mechanism determining the relative prices" (p. 268), and at the end of that proof, state that "we can conclude that in equilibrium we must have $V_2=V_1, \ldots$," (p. 271), where $V_1$ is the market value of an unlevered firm and $V_2$ is the market value of a levered firm. These results may be stated in an analogous manner for firms whose patterns of return differ by a multiplicative constant.

[3] This facet is stated by M-M in Proposition I: "that is, the market value of any firm is independent of its capital structure . . . " (p. 268). This facet is not directly proved by M-M, but it clearly holds.

in the capital structure of a firm if and only if the value of the firm is increased.[4] It follows from *II* that investors are indifferent to changes in the capital structure.

Stiglitz (Sections I and II) demonstrated that the second and third facets hold without the risk class assumption, so that the value of a firm is independent of the capital structure of any firm and all investors are indifferent to changes in capital structure. Default risk, however, can eliminate the equivalence among these three facets, so that while the implication of *I* continues to hold under the conditions I have given, the implications of *II* and *III* are no longer valid in general. Furthermore, shareholders may not prefer a change in capital structure of a firm even if that change increases the value of the securities they hold.

Given the divergence of these three facets, the question of the proper objective for financial management must be raised. The appropriate criterion is that a firm should undertake investments and capital structure changes when they are in the interests of shareholders. Under certain conditions guaranteed by a complete capital market, all shareholders can be shown to be unanimous with respect to their preferences for investment-financing decisions and to prefer an increase in investment (financed by debt) if and only if it increases the value of the equity of the firm. When the capital market is not complete, the investment-financing decisions of a firm can create new patterns of returns in the capital market, and investors will then revise their portfolios resulting in a new capital market equilibrium. Unanimity will then not occur in general, and the criterion of acting in the shareholders' interests will not provide an unambiguous guide for investment-financing decisions.

To investigate these issues, a model that includes those of M-M, Stiglitz, Smith, Hagen, and the author as special cases will be considered. That model is introduced in the next section in which the first facet of the M-M theorem is considered. The second and third facets are considered in Section II where conditions are given under which shareholder preferences will be in accord with changes in the value of the securities held by shareholders. Conclusions are offered in the final section.

## I. Relative Values and Homemade Leverage

The earnings $X_i(\theta)$ of firm $i$, $i=1, 2$, in a risk class are assumed to be given by[5]

$$X_i(\theta) = (1+\theta)k(M_i), \qquad k(0) = 0,$$
$$k'(M_i) \geq 0, \qquad M_i \geq 0$$

where $M_i$ is the investment or scale of the firm and $\theta$ is the net rate of return per unit of $k(M_i)$. Each firm eventually has nonincreasing returns to scale so that $k''(M_i) \leq 0$ for $M_i \geq \overline{M} > 0$. Firm 1 is assumed to be financed only by equity with its value denoted by $V_1$, while the value $V_2$ of firm 2 equals the value $S_2$ of its equity plus the debt $D_2$ that it issues. Firm 2 is assumed to begin with no outstanding debt and then to issue debt $D_2$ at a (gross) interest rate $R_2$ established endogenously in the capital market.

The model will be considered under two assumptions regarding the scale of the firm. First, the scale will be taken to be fixed as considered by M-M, Stiglitz, Hagen, and the author, so that increases in debt represent a purely financial transaction of selling debt and distributing the proceeds to shareholders. In the second case, the initial scale $M^*$ of the firms will be assumed to be fixed with increases in scale financed by debt, so that $M_2 = M^* + D_2$.

An investor $i$ is taken to have an initial endowment consisting of an $\bar{\alpha}_{i1}$ share of the equity of the unlevered firm, an $\bar{\alpha}_{i2}$ share of the equity of the levered firm, and savings (borrowing if negative) of $\bar{m}_i$ that yields the gross risk-free interest rate of one. For the case in which the debt proceeds are distributed to shareholders, the investor chooses

[4] The third facet is not directly stated by M-M but is implied by facet *II* and by their criterion that investments and financing should be judged by their effect on the market value of the firm.

[5] Similar results can be obtained with a more general return function but this formulation is used to correspond with Smith's model.

a new portfolio composition ($\alpha_{i1}$, $\alpha_{i2}$, and $\beta_{i2}$) subject to the budget constraint

$$(1)\quad \bar{m}_i + \bar{\alpha}_{i1}V_1 + \bar{\alpha}_{i2}S_2 = m_i + \alpha_{i1}V_1 + \alpha_{i2}S_2 + (\beta_{i2} - \bar{\alpha}_{i2})D_2$$

where $\beta_{i2}$ is the proportion of the debt of the levered firm purchased. For the case in which the debt is used to finance investment, the budget constraint is that in (1) without the term $(-\bar{\alpha}_{i2}D_2)$.[6] The portfolio return $Y_i(\theta)$ for the investor is (2a) if $-1 \leq \theta \leq \theta^*$ and (2b) if $\theta \geq \theta^*$.[7]

$$(2a)\quad Y_i(\theta) = m_i + \alpha_{i1}(1+\theta)k(M_1) + \beta_{i2}(1+\theta)k(M_2)$$

$$(2b)\quad Y_i(\theta) = m_i + \alpha_{i1}(1+\theta)k(M_1) + \beta_{i2}R_2D_2 + \alpha_{i2}((1+\theta)k(M_2) - R_2D_2)$$

where $\theta^* = R_2D_2/k(M_2) - 1$ is the level of $\theta$ below which the firm defaults on its debt obligations. An investor is assumed to maximize his expected utility $E_iU_i(Y_i(\theta))$ of portfolio return, where $E_i$ denotes expectation with respect to his assessed density function $f_i(\theta)$ and $U_i$ is a strictly concave, measurable utility function. The securities market will be assumed to be competitive in that investors believe that their portfolio decisions do not affect the market values of the securities. Using the budget constraint to eliminate $m_i$, the necessary conditions for an optimal portfolio are

$$(3)\quad \int_{-1}^{\infty} \omega_i(\theta)(1+\theta)k(M_1)d\theta - V_1 = 0$$

$$(4)\quad \int_{\theta^*}^{\infty} \omega_i(\theta)((1+\theta)k(M_2) - R_2D_2)d\theta - S_2 = 0$$

$$(5)\quad \int_{-1}^{\theta^*} \omega_i(\theta)(1+\theta)k(M_2)d\theta + \int_{\theta^*}^{\infty} \omega_i(\theta)R_2D_2d\theta - D_2 = 0$$

where

$$\omega_i(\theta) = U_i'(Y_i(\theta))f_i(\theta) \Big/ \int_{-1}^{\infty} U_i'(Y_i(\theta))f_i(\theta)d\theta$$

is the implicit price of a unit of portfolio return if $\theta$ obtains. Since

$$\int_{-1}^{\infty} \omega_i(\theta)d\theta = 1$$

$\omega_i(\theta)$ represents the marginal rate of substitution between a certain return of one dollar on the risk-free asset and the return $Y_i(\theta)$ when $\theta$ occurs.

These necessary conditions will be attainable if 1) investors may sell short or 2) the optimal portfolio contains positive holdings of the securities of each firm. In these cases a capital market equilibrium is characterized by (3), (4), and (5)[8] for each investor and by the market-clearing conditions $\sum_i \hat{\alpha}_{i1} = 1$, $\sum_i \hat{\alpha}_{i2} = 1$, and $\sum_i \hat{\beta}_{i2} = 1$, where $(\hat{\ })$ denotes optimal. The existence of such an equilibrium is assumed here. Adding (4) and (5) and comparing the resulting expression with (3) indicates that for $M_2 = M_1$, the value of the unlevered firm equals the value of the levered firm.[9] The first facet of the M-M theorem is thus valid in general if investors may sell short or hold positive shares of the securities. In terms of the second facet, if the levered firm may affect its market value by a purely financial transaction, the value of the unlevered firm must change by an equal amount.

Whether or not a purely financial transaction will affect the value of the firms depends on the nature of the capital market. The capital market will be said to be "financially complete" if any pattern of return that a fixed-scale firm may create by a purely

[6] The model studied by Smith will be referred to as a paid-in capital model in that initial holdings $\bar{\alpha}_{i1}$ and $\bar{\alpha}_{i2}$ equal zero and the scale $M_2$ of the firm is determined by the amount $S_2+D_2$ paid in by investors. This model will be considered in Section III.

[7] The net return $\theta$ will be assumed to be greater than or equal to minus one.

[8] This presumes that $Y_i(\theta)$ is positive in the optimal portfolio for all $\theta$ or that if $Y_i(\theta)$ is negative for some $\theta$, the investor can cover the negative return with other assets. Smith considered the case in which $Y_i(\theta)$ negative implies personal bankruptcy, in which case the investor is not able to borrow at the risk-free interest rate.

[9] If the scales of the two firms are different, $M_1 \neq M_2$, then $V_1/k(M_1) = V_2/k(M_2)$.

financial transaction already exists in the market or can be created from existing securities. In that case a change in capital structure will not alter the space of returns available to the investor, and the implicit prices will thus be independent of the capital structure of a fixed-scale firm. The capital market will be financially complete under a variety of assumptions including a complete set of contingent claims markets, a complete set of Arrow-Debreu securities, or a spanning set of securities.[10] Another condition under which the capital market will be financially complete is if investors may create homemade leverage by borrowing using shares of the unlevered firm as collateral.[11] For fixed-scale firms, homemade leverage allows the investor to duplicate the specific pattern of returns generated by the securities of the levered firm, and thus the values of the firms will be equal as indicated in my earlier paper. In the absence of market imperfections the investor may also use homemade leverage to create any pattern of returns that the levered firm is able to create. The capital market is then financially complete, and as will be shown in the next section, both the second and third facets of the M-M theorem hold for fixed-scale firms. If the change in capital structure introduces a "new security" (a new pattern of returns) into the capital market so that the capital market is financially incomplete, the second and third facets will not in general be in accord.

For the case in which the scale of the firm may be changed, the capital market will be said to be "scale and financially complete" if returns identical to those that can be generated by varying the scale of a firm and its financing exist separately in the capital market, can be formed from other securities, or can be created through homemade leverage. For example, if a firm possesses stochastic constant returns to scale ($k'(M)M/k(M)=1$), changes in scale will not alter the set of available returns if there is no default risk. Nonconstant returns to scale may, however, alter the set of available returns if the capital market is not scale and financially complete. The next section considers the relationship between firm valuation and investor preferences in complete and incomplete capital markets.

## II. Firm Valuation and Investor Preferences

### A. *Firm Valuation*

The effect of debt financing on the value of a firm can be investigated by totally differentiating the first-order conditions (4) and (5) to obtain, respectively,

$$(6)\quad dS_2=\int_{\theta^*}^{\infty}\omega_i(\theta)((1+\theta)k'(M_2)dM_2 - (R_2dD_2+D_2dR_2))d\theta + \int_{\theta^*}^{\infty}d\omega_i(\theta)((1+\theta)k(M_2)-R_2D_2)d\theta$$

$$(7)\quad dD_2=\int_{-1}^{\theta^*}\omega_i(\theta)(1+\theta)k'(M_2)dM_2d\theta + \int_{\theta^*}^{\infty}\omega_i(\theta)(R_2dD_2+D_2dR_2)d\theta + \int_{-1}^{\theta^*}d\omega_i(\theta)(1+\theta)k(M_2)d\theta + \int_{\theta^*}^{\infty}d\omega_i(\theta)R_2D_2d\theta$$

where $d\omega_i(\theta)$ is the change in the implicit

[10] The implicit prices may also be independent of the debt level under certain other conditions in which separation results as indicated by Hagen and Frank Milne (1974). The relationship between an Arrow-Debreu model and other models that yield the same type of results, such as those with spanning sets, is developed by Milne (1974), Roy Radner, Steinar Ekern (1974, 1975), Ekern and Robert Wilson, Peter Diamond, and David Cass and Joseph Stiglitz.

[11] This is equivalent to borrowing at a stochastic interest rate $R_1(\theta, Z)$ defined by

$$R_1(\theta,Z)=\begin{cases}(1+\theta)k(M_1)/Z & \text{if } -1\le\theta\le\theta^0(Z)\\ R_1(Z) & \text{if } \theta^0(Z)\le\theta\end{cases}$$

where $R_1(Z)$ is the nominal interest rate on the borrowing, $\theta^0(Z)=R_1(Z)Z/k(M_1)-1$ is the default level for such borrowing, and $Z$ is a size parameter. If $Z=D_2$, then $R_1(Z)$ equals the interest rate on the debt of the levered firm. The investor may thus borrow at the same interest rate as can the firm, as indicated in my earlier paper. Smith, however, has shown that the investor is not able to borrow at the same interest rate as the firm if the investor may pledge only the shares of the levered firm as collateral.

price. Adding the expressions in (6) and (7) yields

$$(8)\quad dV_2 = \int_{-1}^{\infty} \omega_i(\theta)(1+\theta)k'(M_2)dM_2 d\theta + \int_{-1}^{\infty} d\omega_i(\theta)(1+\theta)k(M_2)d\theta$$

For the case of a fixed scale ($dM_2=0$), a purely financial transaction leaves the value of the firm unchanged if the capital market is financially complete (since $d\omega_i(\theta)=0$ for all $\theta$).[12] The values of both firms will thus not be affected by a change in the financial structure of the levered firm, since $V_1 = V_2$.

When the scale is not fixed but the securities market is scale and financially complete, the change in the value of the firm resulting from debt-financed investment may be determined by adding (4) and (5), solving for $\int_{-1}^{\infty} \omega_i(\theta)(1+\theta)d\theta$, and substituting into (8) to obtain

$$(9)\quad dV_2 = k'(M_2)V_2 dM_2/k(M_2)$$

The total value of the firm will thus increase (decrease) as the result of debt-financed investment if the marginal product $k'(M_2)$ is positive (negative).

### B. *Investor Preferences in a Complete Market*

Investors, however, are not directly interested in the value of the firm but rather are concerned with the expected utility resulting from their portfolio return. An investor will prefer a change in the debt level of a firm if and only if that change yields an increase in expected utility. The resulting (normalized) change in expected utility is given by

$$(10)\quad \frac{dE_iU_i}{E_iU_i'} = \int_{-1}^{\theta^*} \omega_i(\theta)dY_i(\theta)d\theta + \int_{\theta^*}^{\infty} \omega_i(\theta)dY_i(\theta)d\theta$$

where

$$dY_i(\theta) = \hat{\alpha}_{i1}(1+\theta)k'(M_1)dM_1 + \hat{\beta}_{i2}(1+\theta)k'(M_2)dM_2 + d\hat{m}_i \quad \text{if } -1 \leq \theta < \theta^*$$

and

$$dY_i(\theta) = \hat{\alpha}_{i1}(1+\theta)k'(M_1)dM_1 + \hat{\alpha}_{i2}((1+\theta)k'(M_2)dM_2 - (R_2dD_2 + D_2dR_2)) + \hat{\beta}_{i2}(R_2dD_2 + D_2dR_2) + d\hat{m}_i \quad \text{if } \theta^* \leq \theta$$

and $\quad E_iU_i' = \int_{-1}^{\infty} U_i'(Y_i(\theta))f_i(\theta)d\theta$

The change in expected utility can be related to the change in the value of the equity of the firm by substituting (6) and (7) into (10) to obtain[13]

$$(11)\quad \frac{dE_iU_i}{E_iU_i'} = d\hat{m}_i + \hat{\alpha}_{i2}dS_2 + \hat{\beta}_{i2}dD_2 + \hat{\alpha}_{i2}\int_{\theta^*}^{\infty} d\omega_i(\theta) \cdot ((1+\theta)k(M_2) - R_2D_2)d\theta + \hat{\beta}_{i2}\int_{-1}^{\theta^*} d\omega_i(\theta)(1+\theta)k(M_2)d\theta + \hat{\beta}_{i2}\int_{\theta^*}^{\infty} d\omega_i(\theta)R_2D_2 d\theta$$

For a purely financial transaction in which the funds raised by issuing debt are distributed to shareholders, the change in investor borrowing (lending) is

$$(12)\quad d\hat{m}_i = (\bar{\alpha}_{i1} - \hat{\alpha}_{i1})dV_1 + (\bar{\alpha}_{i2} - \hat{\alpha}_{i2})dS_2 + (\bar{\alpha}_{i2} - \hat{\beta}_{i2})dD_2$$

With a financially complete capital market and a purely financial transaction, the expression in (11) reduces to

$$(13)\quad \frac{dE_iU_i}{E_iU_i'} = \bar{\alpha}_{i2}dS_2 + \bar{\alpha}_{i2}dD_2 + (\bar{\alpha}_{i1} - \hat{\alpha}_{i1})dV_1 = 0$$

since $dS_2 = -dD_2$ from (9) and thus $dV_1 = 0$.

[12] When the capital market is financially complete, changes in the capital structure of a firm will not alter the investors implicit prices for $\theta$.

[13] The analysis here is analogous to that of Hayne Leland (1973), Theorem V.

All investors therefore are indifferent to a purely financial transaction. The second and third facets of the M-M theorem as stated in the introduction then hold with default risk for fixed-scale firms when the capital market is financially complete.[14]

If the debt is used to finance an increase in the scale of the firm instead of being distributed to shareholders, an initial shareholder ($\bar{\alpha}_{i2}>0$) can be shown to prefer an increase in debt-financed scale if and only if it increases the value of the equity of the firm.[15] This may be demonstrated by substituting the change in investor borrowing (lending)

$$(12') \quad d\hat{m}_i = (\bar{\alpha}_{i2} - \hat{\alpha}_{i2})dS_2 - \hat{\beta}_{i2}dD_2$$

into (11) to obtain

$$(14) \qquad \frac{dE_iU_i}{E_iU_i'} = \bar{\alpha}_{i2}dS_2$$

Since the preferences of all initial shareholders depend only on the sign of $dS_2$, all those shareholders will be unanimous with respect to their preferences for debt-financed investment and will prefer that debt-financed investment if and only if it increases the value of their equity holdings.

The change in the value of the equity of the firm resulting from debt-financed investment may be determined by rewriting (9) as

$$(15) \quad dS_2 = (k'(M_2)V_2/k(M_2) - 1)dD_2$$

The initial shareholder will prefer an increase (decrease) in debt if and only if the value of the firm is greater (less) than the total product divided by the marginal product $k'(M_2)$. The preferred debt level will be that at which $V_2=k(M_2)/k'(M_2)$, and the level of debt that yields this equality will maximize the value of the equity of the firm[16] as well as the expected utility of all initial shareholders. Acting so as to increase the value of the equity of the firm will thus be in the interests of shareholders. Since the optimality condition in (15) is independent of shareholder characteristics, the firm may act to maximize the expected utility of its shareholders without any knowledge of its shareholders except that they are expected utility maximizers.

### C. *Investor Preferences in an Incomplete Market*

If the capital market is neither scale nor financially complete, a purely financial transaction or debt-financed investment will create a new security and a new capital market equilibrium will result. The implicit prices are then not independent of the firm's financing and the above results do not obtain. Further results can be obtained however by substituting (4) and (5) into (10) to obtain[17]

$$(16) \quad \begin{aligned} \frac{dE_iU_i}{E_iU_i'} = {} & \hat{\beta}_{i2}(D_2k'(M_2)dM_2/k(M_2) - dD_2) \\ & + \hat{\alpha}_{i2}(S_2k'(M_2)dM_2/k(M_2) - dS_2) \\ & + \bar{\alpha}_{i2}dS_2 + \bar{\alpha}_{i2}dD_2 \\ & + (\hat{\beta}_{i2} - \hat{\alpha}_{i2})[R_2dD_2 + D_2dR_2 \\ & - R_2D_2k'(M_2)dM_2/k(M_2)] \\ & \cdot \int_{\theta^*}^{\infty} \omega_i(\theta)d\theta \end{aligned}$$

For fixed-scale firms and a purely financial transaction in a financially incomplete capital market, $dM_2=0$, and the expression in (16) is,[18] using $dS_2=dV_2-dD_2$,

$$\begin{aligned} \frac{dE_iU_i}{E_iU_i'} = {} & (\bar{\alpha}_{i2} - \hat{\alpha}_{i2})dV_2 \\ & + (\hat{\beta}_{i2} - \hat{\alpha}_{i2})((R_2-1)dD_2 + D_2dR_2) \\ & \cdot \int_{\theta^*}^{\infty} \omega_i(\theta)d\theta \end{aligned}$$

The preferences of a shareholder will not in

[14] Milne (1975) has provided a similar analysis of the M-M theorem.

[15] Since the scale of firm 1 does not change, $dV_1=0$.

[16] The preferred level of debt-financed investment will be less than that which maximizes the total value of the firm.

[17] For this analysis a capital market consisting only of the securities of one firm and the risk-free asset is considered. If more securities are available, the investor's preferences also depend on the changes in the return and in the values of those securities.

[18] The example given by Hagen involves such an incomplete capital market for which $dV_2/dD_2=dV_1/dD_2 \neq 0$.

general be in accord with the shareholder's gain or loss $((\bar{\alpha}_{i2}-\hat{\alpha}_{i2})dV_2)$ resulting from the change in the value of the firm. If, however, $\hat{\beta}_{i2}=\hat{\alpha}_{i2}$, preferences will be in accord with changes in value only if the investor will sell $(\bar{\alpha}_{i2}-\hat{\alpha}_{i2}>0)$ some of his equity holdings.[19]

For debt-financed investment with no default risk or for the case in which investors hold equal final proportions $(\hat{\alpha}_{i2}=\hat{\beta}_{i2})$ of the bonds and equity of the firm, the expression in (16) is[20]

$$\text{(17)} \quad \frac{dE_iU_i}{E_iU_i'} = \bar{\alpha}_{i2}dS_2 + \hat{\alpha}_{i2}(V_2k'(M_2)dM_2 / k(M_2) - dV_2)$$

The preferences of an investor for debt-financed investment then depend on both the change in wealth due to initial holdings and the marginal gain on the new equity holdings as represented by the last term in (17). This need not, however, be coincident with an increase in the value of the equity of the firm.[21] The model used by Smith involves an incomplete financial market and hence unanimity results do not obtain, in general, as indicated in the following section.

## III. A Paid-In Capital Model

Smith was perhaps the first to consider investor preferences for debt-financed investment. In his model the scale $M_2$ of the firm is obtained by the funds $V_2=(S_2+D_2)$ supplied by investors from their initial wealth (i.e., $\bar{\alpha}_{i2}=0$). Their preferences for debt-financed investment when there is no default risk is then determined from (17) as

$$\text{(18)} \quad \frac{dE_iU_i}{E_iU_i'} = \hat{\alpha}_{i2}(\epsilon - 1)dM_2$$

where $\epsilon=d\ log\ (k(M_2))/d\ log\ (M_2)$ is the elasticity of the total product with respect to paid-in capital. An investor prefers an increase (decrease) in the scale of the firm if the elasticity is greater (less) than one. With constant returns to scale the investor is indifferent to changes in capital structure as indicated by Smith in his Theorem 1. In the terminology utilized in this paper, the capital market in Smith's model is scale and financially complete if $\epsilon=1$ for all $M_2$. If $\epsilon\neq 1$, changes in scale introduce a new security (pattern of return) into Smith's capital market even if there is no default risk, so the capital market is incomplete.

With default risk the capital market is incomplete in Smith's model, and an increase in debt is preferred if and only if[22]

$$\text{(19)} \quad \frac{dE_iU_i}{E_iU_i'} = (\hat{\beta}_{i2} - \hat{\alpha}_{i2})A > 0$$

where

$$A = (D_2dM_2/M_2 - dD_2) + (R_2dD_2 + D_2dR_2 - R_2D_2dM_2/M_2)\int_{\theta^*}^{\infty} \omega_i(\theta)d\theta$$

Consequently, if there is default risk, the investor under Smith's assumptions will be indifferent to changes in the debt level of the firm only if either $\hat{\beta}_{i2}=\hat{\alpha}_{i2}$ or $A$ equals zero. Letting the investor's debt holdings be $D_{i2}^0=\hat{\beta}_{i2}D_2$ and equity holdings be $S_{i2}^0=\hat{\alpha}_{i2}S_2$, the investor with $\hat{\alpha}_{i2}=\hat{\beta}_{i2}$ is indifferent to a change in the debt level if $D_{i2}^0/S_{i2}^0=\mu$, where $\mu$ is the debt-equity ratio of the firm. Thus if the firm's debt-equity ratio is equal to the ratio of the investor's holdings of the firm's debt and equity, the investor is indifferent to changes in the debt level of the firm. This is in accord with Smith's Theorem 2 for the case of stochastic constant returns to scale. If, however, $\mu\neq D_{i2}^0/S_{i2}^0$, the preference of the individual cannot be predicted without

[19] If all investors have identical expectations and all have quadratic utility functions, for example, every investor will hold the same proportion of all securities. Under these strong assumptions the implicit prices are independent of the change in the capital structure and $dV_2=0$.

[20] With a scale and financially complete capital market the last term in (17) is zero from (12).

[21] Additional results can be obtained by analyzing the capital market at an *ex post* equilibrium in which investors already hold optimal portfolios; i.e., $\bar{\alpha}_{i2}=\hat{\alpha}_{i2}$ and $\bar{\beta}_{i2}=\hat{\beta}_{i2}$ where the bonds are considered as having been retraded. Leland (1974) and Ekern (1974) have analyzed such a case and have developed unanimity results.

[22] The condition in (19) is obtained by letting $dM_2=dD_2+dS_2$, $S_2=M_2-D_2$, and simplifying.

knowledge of his portfolio holdings, utility function, and probability assessments. A shareholder will prefer an increase (decrease) in the firm's debt if

$$(20) \qquad \mu > (<) D_{i2}^{0}/S_{i2}^{0} \quad \text{and} \quad A < 0$$

$$\text{or} \qquad \mu < (>) D_{i2}^{0}/S_{i2}^{0} \quad \text{and} \quad A > 0$$

The result given by Smith in Theorem 2 differs from that in (20) because he stated the preferences in terms of the debt-equity ratio instead of the debt level and because he assumed that the nominal interest rate on the firm's bonds was independent of the debt-equity ratio.

## IV. Conclusions

The appropriate criterion for financial and investment decisions is to take those decisions that are desired by shareholders. Determining what actually is in the interests of shareholders is in general difficult, since an investor's preferences depend on his utility function, probability assessments, and portfolio holdings. When, however, the proposed financing or investment by a firm does not alter the available returns in the capital market, the implicit prices for every investor will be unaffected by the proposals, and all shareholders will have unanimous preferences regarding such proposals. All investors then are indifferent to an alteration in the capital structure of a fixed-scale firm, and the value of that firm is independent of its capital structure. For variable-scale firms all shareholders prefer an increase in debt-financed investment if and only if it increases the value of the equity of the firm. In this case the firm may act in the best interests of its shareholders by maximizing the value of the equity of the firm. The second and third facets of the M-M theorem thus obtain.

If the financing–investment alters the space of available returns in the capital market, the implicit prices will depend on the firm's decisions except under certain special assumptions such as those that lead to separation. When the implicit prices are not independent of the firm's proposals, a purely financial transaction by one fixed-scale firm will change the value of all fixed-scale firms in a risk class by the same amount, since those firms must have the same value. With a variable scale the value of a firm will depend both on its financing and its investment opportunities. In such cases where the implicit prices are not independent of the decisions of the firm, the firm is without a guide as to how to work in the best interests of shareholders, since the best interests of shareholders are not in general coincident with changes in the value of the equity of the firm. Also, shareholders will not in general be in agreement with respect to their preferences for the proposals of a firm, and the firm is then without an unambiguous criterion for its financial and investment policies.

# The Xistence of X-Efficiency

*By* GEORGE J. STIGLER*

Harvey Leibenstein called attention in an influential article (1966) to a source of economic inefficiency which was given the awful name of X-[in]efficiency. He cited studies in which misallocations of resources due to monopoly or tariffs had trifling social costs, whereas simple failure to attain the production frontier apparently led to social losses of a vastly greater magnitude. I propose to argue that this type of inefficiency can usefully be assimilated into the traditional theory of allocative inefficiency.

It is a question (to be discussed below) whether one ascribes failures to reach the ultimate limits of output from given inputs in any state of technology to inadequacy of knowledge alone, or adds also inadequate "motivation." Leibenstein (1966) separates the two:

> It is obvious that not every change in technique implies a change in knowledge. The knowledge may have been there already, and a change in circumstances induced the change in technique. In addition, knowledge may not be used to capacity just as capital or labor may be underutilized. More important, a good deal of our knowledge is vague. [pp. 404–05]

He ascribes increases in X-efficiency to 1) increases in motivational efficiency—workers are stimulated by incentive pay, or management by competition or other adversities; and 2) improvements in the inefficient markets for knowledge. I shall first deny the propriety of treating changes in motivation as a source of changes in output, and then proceed to the question of knowledge.

### I. Motivational Losses

Leibenstein (1973) has emphasized that X-inefficiency arises largely from losses of output due to motivational deficiencies of resource owners:

> [F]or the same set of human inputs purchased and the same knowledge of production techniques available to the firm, a variety of output results are possible. If individuals can choose, to some degree, the APQT bundles [choice of Activity, Pace, Quality of work, Time spent] they like, they are unlikely to choose a set of bundles that will maximize the value of output. [p. 768]

If management seeks to impose output-maximizing *APQT* bundles on the workers, indeed, these assignments of tasks would likely be " . . . less efficient than those that individuals would choose themselves under an acceptable set of [managerial] restraints" (p. 769).

In this case, and in every motivational case, the question is: what is output? Surely no person ever seeks to maximize the output of any one thing: even the single proprietor, unassisted by hired labor, does not seek to maximize the output of corn: he seeks to maximize utility, and surely other products including leisure and health as well as corn enter into his utility function. When more of one goal is achieved at the cost of less of another goal, the increase in output due to (say) increased effort is not an increase in "efficiency"; it is a *change* in output.

The concept of motivational efficiency seems to extend also to the task of getting a "predetermined output" from hired factors (see Leibenstein, 1966, pp. 408, 412). There are important and pervasive problems in all contracts between people, in seeking the fulfillment of the reciprocal contractual promises, and substantial resources are necessary to enforce the agreements (see Armen Alchian and Harold Demsetz). Both the avoidance of unpleasant tasks and the enforcement activity designed to curtail this avoidance can be carried on to the utility-maximizing degree and generate no inefficiency in producing utility. Output and utility would be larger if resources were not

* Graduate School of Business, University of Chicago.

necessary to the enforcement of contracts, but output and utility would also be larger if water boiled at 180°F or a day had 25 hours. New techniques of contract enforcement may be as productive as other improvements of technology.

Thus X-inefficiency attributed to motivational factors characterizes as inefficiency either the existence and pursuit of other desired outputs or the expenditure of resources required for the optimal enforcement of contracts. This tunnel vision of output seems entirely unrewarding: it imposes one person's goal upon other persons who have never accepted that goal. There is no waste in this sort of X-inefficiency: waste is a foregone product that could be acquired for less than its cost.

Leibenstein achieves much of the importance of motivation in X-efficiency by that ancient and powerful scientific technique, definition. When he copiously illustrates that "changes in incentives will change productivity per man" (1966, p. 401), he is assigning motivation an independent role whereas ordinary economic language would classify the methods of remuneration of employees as a part of the state of technology. Again, when an Egyptian petroleum refinery becomes more "efficient" with a change of management, we are told that "It is quite possible that had the motivation existed in sufficient strength, this change could have taken place earlier" (1966, p. 398). Potential motivation could indeed rewrite all history: if only the Romans had tried hard enough, surely they could have discovered America. (Thus motivation can be invoked to explain every unperformed task that is physically possible, no matter how unrewarding.) We may sympathize with Leibenstein's desire to associate his X-efficiency with economic behavior, but this shotgun marriage is not fertile.

## II. The State of Technology

The near-universal tradition in modern economic theory is to postulate a maximum possible output from given quantities of productive inputs—this is *the* production function—and to assert that each firm operates on this production frontier as a simple corollary of profit or utility maximization. The merit of this conventional tradition is also its demerit: it eliminates the problem of the choice of technology.

Alfred Marshall followed an entirely different approach, and it is remarkable that he had virtually no followers. He proposed to characterize production possibilities by the *average* outputs obtained from given inputs, and in particular labelled the user of this average relationship the Representative Firm:

> We shall have to analyse carefully the normal cost of producing a commodity, relatively to a given aggregate volume of production; and for this purpose we shall have to study *the expenses of a representative producer* for that aggregate volume. On the one hand we shall not want to select some new producer just struggling into business, who works under many disadvantages, and has to be content for a time with little or no profits, but who is satisfied with the fact that he is establishing a connection and taking the first steps towards building up a successful business; nor on the other hand shall we want to take a firm which by exceptionally long-sustained ability and good fortune has got together a vast business, and huge well-ordered workshops that give it a superiority over almost all its rivals. But our representative firm must be one which has had a fairly long life, and fair success, which is managed with normal ability, and which has normal access to the economies, external and internal, which belong to that aggregate volume of production; account being taken of the class of goods produced, the conditions of marketing them and the economic environment generally. [p. 317, and Bk. IV, ch. 13]

Marshall suggested two causes of variation among firms in costs of a given output: the age of the firm (which he emphasized), and variations in entrepreneurial capacity. Strictly speaking, the latter element (the departure from "normal ability") is inappropriate: differences in quality of an input do not lead to differences in outputs from given inputs.

The reason Marshall's approach was not adopted by the science is lucidly presented in the leading attack that was made on the

representative firm by Lionel Robbins. In a once-famous essay, Robbins argued persuasively that when costs of firms differed because of quality of entrepreneurs (or other inputs), the differences in productivity would be reflected in differences in profits (or other input prices). Just as differences in efficiency of workers are reflected in their wages, so differences in entrepreneurial skills (including the choice of technology) will be reflected in their "profits." He states:

> There is no more need for us to assume a representative firm or representative producer, than there is for us to assume a representative piece of land, a representative machine, or a representative worker. [p. 393]

Robbins was of course correct: the Representative Firm is not needed to reconcile the existence of differences among entrepreneurs with the existence of stable competitive equilibrium.

What one may lament, however, is the failure of Robbins and Leibenstein, and all of us in between, to recognize the problem of determining which technologies will be used by each firm (and, for that matter, each person). The choice is fundamentally a matter of investment in knowledge: the costs and returns of acquiring various kinds and amounts of technological information vary systematically with various characteristics of a firm: its size, the age of its present capital assets, the experience of its managers, the prospects of the trade. No attention has been paid by economists to the analysis of the optimal amount of technological knowledge that a firm should possess. Leibenstein deserves credit for reviving this Marshallian question, but his attention to X-inefficiency as the explanation is an act of concealment: it simply postulates the differences in technology among firms which should be explained.

### III. The Interpretation of Output Differences

We observe two farmers with reasonably homogeneous land and equipment, who nevertheless obtain substantially different amounts of corn. We measure this corn output over some period of time to reduce the effects of stochastic variation (i.e., unenumerated inputs such as weather). The observed variation is due, perhaps, to differences in knowledge, including the knowledge of technology or the knowledge of how far to carry the application of each productive factor. The farmers will differ in the cost of learning new things or the expected returns from new knowledge—one may be planning to leave agriculture shortly—so they "rationally" devote different amounts of resources to acquiring knowledge. Or one is simply more intelligent than the other, and learns more quickly or thinks more precisely (for example, makes fewer mistakes in arithmetic).

The effects of these variations in output are all attributed to specific inputs, and in the present case chiefly to the differences in entrepreneurial capacity. In neoclassical economics, the producer is always at a production frontier, but his frontier may be above or below that of other producers. The procedure allocates the foregone product to some factor, so in turn the owner of that factor will be incited to allocate it correctly.

Leibenstein does not attempt to understand the allocation of "inefficient" resources, and hence does not see the necessity for attributing his X-inefficiency to specific inputs. Just as automobile accidents are palpable inefficiencies to many people so X-inefficiency is a palpable inefficiency to Leibenstein. But accidents and "inefficiencies" are associated with returns as well as costs, and a useful theory must take both sides of their roles into account.

Indeed, Leibenstein's apparatus does not allow him to analyze effectively concrete economic problems. Consider his argument that monopoly is less efficient than competition. To reach this result, he must assume that 1) monopolists do not maximize profits, and 2) competitors are driven closer to "the" minimum costs by the entry of new rivals, some of whom are efficient, by a Darwinian process. The first assumption is an abandonment of formal theory, and one which we shall naturally refuse to accept until we are given a better theory. It "solves" the question of the effect of monopoly on efficiency without argument or evidence. The latter assumption of competitive selection coolly

ignores the problem of general equilibrium (where do the driven-out entrepreneurs go?, and where do the efficient entrepreneurs come from?), and fails to demonstrate (or even to argue) that inflows and outflows of entrepreneurs of various qualities will converge on a high-efficiency equilibrium in each competitive industry.

Earlier I defined waste as the situation in which foregone products could be obtained for less than they cost. Waste can arise *ex post* because *ex ante* plans rested upon erroneous predictions. This type of waste is unavoidable, although its magnitude is subject to control. Waste can also arise in the absence of uncertainty if the economic agent is not engaged in maximizing behavior. Unless one is prepared to take the mighty methodological leap into the unknown that a nonmaximizing theory requires, waste is not a useful economic concept. Waste is error within the framework of modern economic analysis, and it will not become a useful concept until we have a theory of error.

# A Note on Quantitative Restrictions and Capital Mobility

By RODNEY E. FALVEY*

The link between international factor mobility and commodity trade has received some attention in recent years. In the main, this analysis has served to extend and "tighten" Robert Mundell's original demonstration of the basic substitutability between goods and factor movements in the standard trade model,[1] and to expand the discussion to examine the interaction between commodity and factor taxation.[2] In the absence of impediments to factor movements (physical restrictions or differential taxation on foreign and domestic earnings), any import tariff is prohibitive, in the sense that the factor flows it induces will eliminate international commodity exchange.[3]

Unless both commodity and factor taxation are possible, it appears a country has little influence over the composition of its trade or domestic production. When factors are immobile, the optimal policy to achieve some desired production level other than the free trade level is to use the appropriate production tax-subsidy scheme. With factor mobility, however, this runs into the same problems as the tariff and would eventually force the country to specialize in the protected industry. But tariffs (or price restrictions) represent but one major form of commercial policy. Previous analysis has neglected the other—quantitative restrictions.

The object of this note then is two-fold. First to demonstrate that quantitative restrictions on commodity trade will permit a country to influence its trade and production patterns, despite factor mobility, and without requiring distortions in both factor and commodity markets. Second, while doing this, to demonstrate the basic differences in the adjustment processes under these two commercial policy regimes. Although, in a static framework they are essentially equivalent, once factor mobility is introduced the distinction between a price and a quantity restriction becomes important. This last result is quite general and readily extends beyond the confines of the structure examined here. I begin by briefly considering the effects of an import tariff on trade and production in this system, and then go on to compare this with the effects of an import quota.

Suppose the world is composed of two countries (home and foreign), each of which produces two goods (the home exportable $X_e$ and the home importable $X_m$), through the services of two factors of production (labor and capital). Assuming identical linear homogeneous technologies in each country, let the factor endowments be such that the initial free trade equilibrium implies factor price equalization. Thus, although capital is assumed internationally mobile, there exists no incentive in the form of a return differential for it to move. There are two aspects of this equilibrium which are important for future results: First, the allocation of capital between the two countries which would give this equilibrium is not unique.[4] Second, within a certain range,[5] shifting capital from

* Assistant professor of economics, Virginia Polytechnic Institute and State University. I am indebted to Rudiger Dornbusch, Michael Mussa, and a referee for comments and suggestions.

[1] See Mundell and, for example, Frank Flatters, Douglas Purvis, and Melvyn Krauss. Certain ambiguities can arise if both factors are internationally mobile, however. First, determining what it is that defines a country (usually its endowment), and second, if tastes are different in the two countries, determining who it is that holds these tastes.

[2] See Ernest Nadel. Particularly when the assumption of identical technologies is relaxed—see Ronald Jones and John Chipman.

[3] A one-way commodity flow will still occur, however, if foreign earnings are repatriated. Alternatively, the import restriction could force specialization in production of the importable.

[4] There is a range of "endowment allocations" for which the same total world production, relative prices and factor returns could occur. See Robert Warne.

[5] Depending on how close each is to specialization initially. Again see Warne.

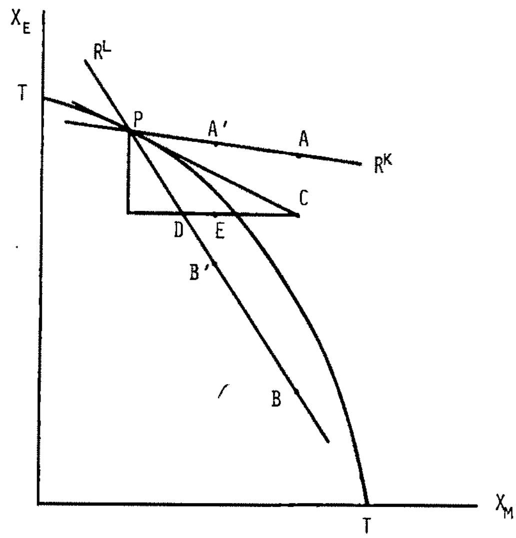

FIGURE 1

one country to the other simply changes the location of production without altering its total, because of linear homogeneity.

For convenience, it is assumed both countries own their entire initial domestic capital stocks, and, in what follows, that any foreign earnings on capital will be repatriated in full. This initial equilibrium is demonstrated for the home country in Figure 1. As shown, $TT$ is the domestic production-possibility frontier for its initial endowments of factors; $P$ represents the free trade production point; and $C$ the consumption point, when the terms of trade are represented by the tangent at $P$.

Now let the home country place a tariff on its imports with any tariff proceeds being redistributed in a neutral manner. Imagine, for a moment, capital is immobile. Then, barring a Metzler Paradox,[6] the domestic relative price of the importable would rise and the home terms of trade improve. Thus, relative prices would move in opposite directions in the two countries, and the real return to the factor used relatively more intensively in the production of the home importable would increase at home and decline abroad.[7] Conversely for the other factor.

Should capital's domestic return tend to rise, the home country will experience a capital inflow, otherwise a capital outflow. In either event, the force of the resulting capital movement is toward expanding domestic production of importables, independent of factor intensities. Foreign production of their exportable correspondingly contracts. This capital flow will continue as long as the international differential in rentals exists—that is, until either the home country becomes specialized in the production of the importable, or commodity prices return to their original levels.[8] Neglecting specialization, the price and rental differential persists until production changes have eliminated trade in the importable (whence the tariff becomes redundant). At this point world prices, incomes, and hence, desired consumption will have returned to their initial levels (i.e., $C$ in Figure 1).

Consider the two alternative intensity assumptions.

1) The importable is capital intensive. At constant commodity prices, the capital inflow following the tariff shifts the corresponding production point along the Rybczynski line $R^K$, until point $A$ is reached. At $A$, domestic production of the importable is just sufficient to satisfy desired consumption at free trade prices and thus imports cease. The quantity $CA$ of the exportable represents the income to foreign-owned capital.

2) The importable is labor intensive. At constant commodity prices, capital leaves shifting the production point down the Rybczynski line $R^L$, until $B$ is reached. Here the home country is self-sufficient in the importable and receiving $BC$ of the exportable as income from its foreign investments.[9]

[6] A possibility under a tariff regime but precluded by an import quota—see the author. The results are unaffected by this possibility however.

[7] The Stolper-Samuelson Theorem: see Wolfgang Stolper and Paul Samuelson.

[8] Since the thrust of the capital movement is toward reduced foreign production of their exportable, trade will be eliminated long before the foreign country could become specialized.

[9] If the tariff did not apply to earnings repatriated in units of the importable, the new production equilibrium could be at $D$, where the home country is self-sufficient in the exportable, or at any point on $DB$.

Basically the reason the solution goes this far is as follows. When both countries are nonspecialized in this model, factor returns depend on commodity prices and the technology alone, and thus are unaffected by the capital movements in themselves. The shift in capital from one country to the other merely serves to shift the location of production without altering its total. What this result illustrates is the basic substitutability between commodity and factor movements in this model. Any tariff, by creating a fixed price distortion between the two countries, prompts counteracting capital flows which eliminate trade.

A tariff alone is not a flexible instrument in these circumstances. With unrestricted capital movements, any tariff is prohibitive. There are but two production levels the country can choose—"free trade" or "no trade." A dilemma then arises if our country desires production at some intermediate point.[10] Can this be achieved without distorting both factor and commodity markets? The solution lies in quantitative restrictions. While a tariff creates a constant price differential between the two countries as long as any trade in the importable occurs, an import quota distorts prices only to the extent trade is restrained by the quota. By imposing the appropriate import quota, our country can shift production of the importable to any level between the free trade and no trade production levels it chooses. For example, consider a quota limiting imports to the level shown by distance *EC* in Figure 1. In the absence of capital mobility, this forces the domestic relative price of the importable to rise above its free trade level, expanding production and discouraging demand to the extent necessary to reduce imports to the quota level. Conversely, the relative price of the home importable will fall in the foreign country. Again, we have two alternative pressures on factor returns, depending on which factor is used intensively in production of the importable. In either case, domestic import competing production will expand as a consequence of the resulting capital movement. Here the difference between a price and a quantity distortion becomes important. As long as the quota is binding, it separates the markets for the home importable in two countries and the location of production is no longer immaterial.

As production of the home importable shifts with the capital flow from the foreign to the home country, we get an excess supply at home and an excess demand abroad at the initial postquota prices. The relative price of the domestic importable tends to fall at home and rise abroad, pulling the real returns to capital closer together in the two countries. Thus, unlike the tariff, under a quota regime the flow of capital is able to influence the differential in the real returns to capital through the resulting shifts in the location of production.

As before, this capital flow continues until returns are equalized. Again, barring specialization, this occurs when relative prices return to their former levels. However, unlike the tariff, imports are not eliminated but simply reduced to the level established by the quota where the price and return differentials, and hence the incentive for further capital movements are eliminated. In Figure 1, we are now back at free trade prices, produced either at $A'$ or $B'$.

This demonstrates that quantitative restrictions retain their "flexibility" in forcing production adjustments, despite the possibility of capital movements.[11] An import tariff and quota pair which will be equivalent with capital immobile are no longer equivalent when capital can move. The rigid price differential forced by the tariff persists as long as trade in the importable exists. With the quota, however, a price differential exists only to the extent trade is limited by the quota. So any tariff has as its equivalent the prohibitive quota.

[10] Perhaps in pursuit of some "noneconomic objective." For a discussion of such objectives, see Jagdish Bhagwati. Note I am assuming our country is unconcerned about capital movements per se.

[11] Note, however, that while the quota is a flexible instrument with respect to the national origin of production, it remains ineffective with respect to factor rentals and goods prices. The main thrust of Mundell's argument, that capital mobility frustrates attempts to alter prices and rentals, is unchanged.

The adjustment process also differs under the two regimes, since the link between product, and hence factor, prices in the two countries is fixed under the tariff but free to vary with the capital movements under the quota. Thus, as the capital flows occur, they exert a direct effect reducing the return differential under the quota but not under the tariff. This property will carry over to more complex structures where capital's return depends on both relative prices and the capital "endowment." Now capital flows will have a direct influence on the return to capital, independent of any change in relative prices that may occur. In addition the pattern of relative prices in the two countries converging with the capital flow under the quota, yet remaining separated by a fixed wedge under the tariff, will persist. Given this, in such a more general structure one expects smaller flows and production shifts under the quota regime.

# Black-White Differences in Returns to Schooling: Some New Evidence

By Charles Link, Edward Ratledge, and Kenneth Lewis*

During the 1960's it was generally believed that policies of providing additional education would go a long way toward equalizing the large income differentials between blacks and whites. But in light of recent studies on the subject, serious doubt has been cast on the sanguine view toward education's ability to accomplish income equality (see Giora Hanoch, Randall Weiss, and Lester Thurow). While most research has centered on returns to *years of education*, Christopher Jencks has gone even further to argue that the *quality* of education has a negligible part to play in the process. Recently, however, the studies by Leonard Weiss and Jeffrey Williamson, Link and Ratledge, and Finis Welch have yielded more optimistic findings regarding the rôle of educational quality on black-white earnings differences.[1]

The present note deals specifically with the recent article by Welch. He presents evidence suggesting that blacks for the past several years have finally begun to receive monetary benefits from education commensurate with those of whites. Most importantly, he argues that this change is due to an increase in the quality of black education. Welch observes in his earnings equations a decline in the coefficient of the years of schooling variable ($\hat{a}$) for older cohorts of blacks and whites in his samples.[2] More important from Welch's point of view, the rate of decline in ($\hat{a}$) is larger for blacks than whites, implying blacks are catching up. It is the catching up which Welch attributes to increased quality of education for blacks.

There are several potential interpretations of Welch's results. One is that life cycle or credential effects may be present that lessen the impact of schooling on earnings as one is out of school longer.[3] However, even if life cycle effects are nonexistent, two additional explanations of the greater dropoff for blacks are possible. On the one hand, changes in the quality of education may cause higher returns to an additional year of schooling for blacks than whites. In other words, Welch's "so-called" vintage effect is greater for blacks than whites Alternatively, the quality of education may be rising more quickly for blacks than for whites.[4]

The regression results presented below indicate that the vintage effect is only slightly larger for blacks, corroborating Welch's hypothesis that improved quality of black education is indeed responsible for blacks' relative income gains. Similar to Welch's findings, life cycle effects are nonexistent for the sample of young males analyzed below.

We would like to thank the anonymous referee and George Borts for comments on earlier drafts of the paper. The research was made possible by a UNIDEL grant from the University of Delaware.

[1] James Morgan and Ismail Siragelden as well as Frank Stafford and George Johnson found a positive association between average state expenditures per student in elementary and secondary education and subsequent earnings for whites.

[2] Welch utilizes samples of urban males from the 1 in 1000 sample of the 1960 Census and the 1966 Survey of Economic Opportunity.

[3] Thurow (1972) has argued that the impact of education on earnings does not arise from the cognitive skills imparted to an individual but is instead the result of the information it provides the employer about the trainability of the prospective employee. Thus as one gets further away from school, experience would become more important. Welch argues that life cycle effects are small and to support his claim makes cohort comparisons involving the direct effects in 1959 and 1966; within cohort groups he finds that the effects of schooling do not diminish over time.

[4] The three propositions discussed in the text are developed in a technical appendix available on request from the authors. Of course, the increases in the education coefficient for younger cohorts may reflect less discrimination in the labor market.

above, an earnings regression is estimated which directly incorporates a measure of elementary and secondary educational quality. The data are derived from the National Longitudinal Survey of the Labor Force which is being conducted by the Center for Human Resources Research at the Ohio State University under contract to the U.S. Department of Labor. The sample utilized consists of 1,562 males who were between the ages of 17 and 27 in 1969; and it includes 326 young blacks and 1,236 young white males who were out of school at least one year in 1969

The advantages of the data are threefold. First, they supply a proxy for the quality of elementary and secondary education received by each respondent. Second, blacks were oversampled by a factor of three, allowing greater precision in a statistical analysis of their labor force behavior. Finally, because the sample is composed of young males, we can examine the cohort of blacks which Welch argues has been the main beneficiary of increased educational quality.

The dependent variable is 1969 annual wages and salaries ($Y$). Explanatory variables included in the regression are: the natural logarithm of the number of weeks worked ($ln\ W$); potential labor market experience designated as age—education—5, subject to the constraint the useful experience starts at age 16 (*Exper*); experience squared $(Exper)^2$; an interaction between years of schooling ($S$) and the natural logarithm of expenditures per student as of 1968 in the district where the respondent went to high school (*ln Expend*); and an interaction between years of schooling ($S$) and experience (*Exper*). The two interactions allow us to determine whether or not Welch's "vintage" effect (i.e., $\partial\ ln\ Y/\partial S = f$ (quality)) and life cycle effects $(\partial\ ln\ Y/\partial S) = g$ (experience)) are present. A positive sign is predicted on the coefficient of $S$ x *ln Expend* and a zero or negative sign on the coefficient of $S$ x *Exper*.

The interaction between $S$ and *ln Expend* is employed instead of the additive variable years of schooling because units of education should be conceptually viewed as being the product of the years of schooling ($S$) and quality of education (*ln Expend*).[5] The unweighted schooling variable is in fact inappropriate unless the quality of a year of schooling is approximately the same for everyone in the sample.

TABLE 1—EARNINGS MODELS INCLUDING *ln* EXPENDITURES/STUDENT[a]

| Variable | White | Black |
|---|---|---|
| Weeks | .961[b] | .871[b] |
| | (.040) | (.059) |
| Experience | .290[b] | .149 |

| Experience Square | −.015[b] | −.008[c] |
| | (.002) | (.004) |
| Schooling x Expenditures | .017[b] | .019[b] |
| | (.002) | (.005) |
| Schooling x Experience | −.003 | .000 |
| | (.003) | (.007) |
| Constant | 2.729 | 3.083 |
| Adjusted $R^2$ | .56 | .51 |

[a] Standard errors in parentheses.
[b] Significant at 1 percent level.
[c] Significant at 5 percent level.

Expenditures on education rose rapidly during the 1960's implying that our expenditure measure most likely overstates expenditures for young males educated prior to 1968. The coefficient of the schooling-expenditures interaction is likely to be biased downward. In other words, when these overstated expenditures (for those educated before 1968) are associated with *low* earnings in 1969, the observed relationship will tend to "wash out." If, as Welch (p. 901) suggests, expenditures per student on blacks have risen relative to whites, the bias will even be larger in the black equations.

The results of the earnings regressions are shown in Table 1.[6] The main coefficients of interest are those attached to the interactive variables $S$ x *ln Expend* and $S$ x *Exper*. Of

[5] Welch (p. 896) also recognizes this point, but data limitations prevented him from using the preferred formulation.

[6] Covariance analysis reveals that the structure of the black and white equations are significantly different at both the 1 and 5 percent levels of significance, even when we allow for differences in the black-white intercepts.

these only the former is significant at the 5 percent level. Most importantly the results in Table 1 confirm the existence of a vintage effect (i.e., $\partial \ln Y/\partial S = f$ (quality)). Second, the effect appears to be at least as large for blacks (.019) as whites (.017).[7] The data do not reflect life cycle effects, which is not surprising since the sample has a range of only eleven years of experience.

The major findings of the study indicate, as Welch suggested, that the great increase in returns to black versus white education is due to changes in the quality of education as opposed to differential vintage effects.[8] In addition, the interactive relationships for blacks exhibited between years and expenditures may partially explain the pessimistic finding of education's lack of impact on earnings of blacks found by researchers using the 1960 data. At the least the findings suggest that there is still a role for the quality of education to play in reducing black-white earnings differences. Of course a definitive statement on the issue awaits further research. However, even though Welch raised more questions than he answered, it appears that his major conclusions still hold and provide the basic hypothesis upon which future research can be based.

[7] The black-white differential is understated to the extent the black expenditure component of the interaction term reflects a larger downward bias compared to that of whites.

[8] The conclusions regarding quality remain when the sample is divided into groups of urban blacks and whites.

# The Effect of Compensated Price Changes on Expenditures

*By* C. Robert Wichers*

After a compensated or overcompensated increase of the price of a commodity, the consumer buys fewer units of that commodity. Does he pay more for those fewer, more expensive units, or less? The Slutsky equation holds no answer (see John Hicks, p. 36). It will be shown, however, that an answer can be found through a slightly different definition of (over)compensation. Specifically, if a change of the price of a commodity is accompanied by (over)compensation *in terms of that commodity*, the consumer's expenditure for that commodity will change in a predictable direction (opposite to the direction of the price change, in fact). This is an empirically verifiable result.

Compensation or overcompensation in terms of commodities is of course less efficient in the welfare-theoretical sense than compensation or overcompensation in terms of money. This consideration plays no role here, however. The sole purpose of this paper is to establish an empirically verifiable result.

The result to be proved can be geometrically illustrated—quite easily so when money is treated as one of the utility-carrying commodities, less easily when money is not so regarded. (Either way, the result holds.) Only the easy case is sketched here. Figure 1 depicts a situation with two utility-bearing commodities, one of which is money. The individual's budget line is marked *I*, his initial bundle is $x^0$, and the equilibrium bundle is $x$. When $p_1$ increases, and a compensating quantity *of good 1* is added to the initial bundle $x^0$, the initial bundle becomes $\bar{x}^0$. At the same time, the budget line becomes the line marked *II*, and the equilibrium bundle becomes $\bar{x}$. As can be seen in Figure 1, the consumer now buys less of good 1 than before ($b\bar{x}<ax$) *and* pays less money than before ($b\bar{x}^0<ax^0$). (Compare the more conventional situation of Figure 2, where compensation is made in terms of money. Here, too, the compensated price increase induces the consumer to buy less of good 1 than before ($b\bar{x}<ax$), but it is not clear whether the consumer pays less money than before, or more, or exactly as much ($b\bar{x}^0 \lesseqgtr ax^0$).)

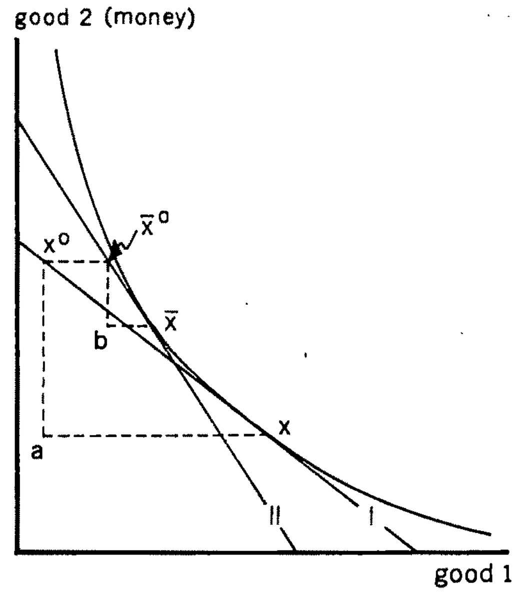

Figure 1. Compensation in Terms of Good 1

It may appear strange, at first glance, that there should be a difference between the effects of compensation in terms of money and compensation in terms of a commodity. For if the consumer is given a few units of commodity $i$ to make up for an increase of $p_i$, he could begin by exchanging those units for money, after which the situation would be conventional. The point is, however, that such an initial exchange may be counted as part of the consumer's transactions. Only if it is so counted—and in Figure 1 it is—will the effect of a compensated price change on expenditures be predictable.

The rest of the paper consists of two sections. In Section I, the result described is

* Assistant professor of economics, State University of New York at Stony Brook. I should like to thank the referee for his helpful comments.

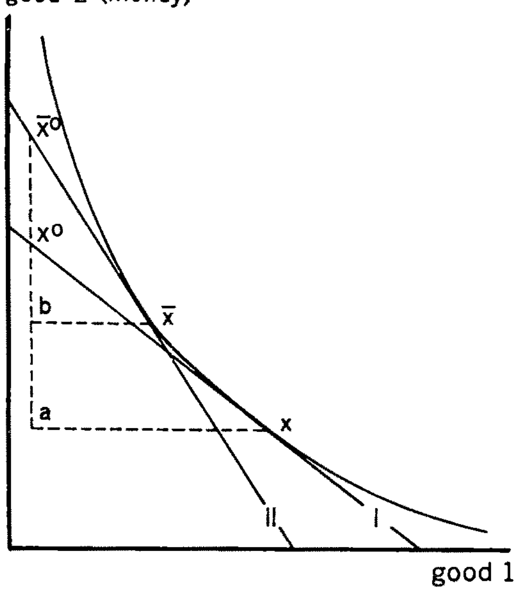

FIGURE 2. COMPENSATION IN TERMS OF GOOD 2

proved for the case of a compensated price change. In Section II, the result is proved for the case of an overcompensated price change, that is, a price change accompanied by such a change of the initial bundle that the old equilibrium bundle becomes reattainable. The overcompensated case is also easy to illustrate geometrically; Figure 1, slightly changed, could serve. Details are omitted.

### I. Effects of a Compensated Price Change

Consider a consumer in a market where $n$ commodities and money are exchanged. Money is regarded as a noncommodity, except when explicitly specified otherwise. Commodity bundles are denoted generically by $\{x_1, \ldots, x_n\}$ or $x$, except for the consumer's initial bundle, written $\{x_1^0, \ldots, x_n^0\}$ or $x^0$. The equilibrium bundle will be represented by $x$; confusion with bundles in general seems unlikely.

In addition to the bundle $x^0$, the consumer brings an amount of money to the market. This amount is $m$, say; the budget constraint is then given by

$$\sum p_j x_j = \sum p_j \overset{0}{x_j} + m$$

or

$$p'x = p'x^0 + m$$

The consumer's behavior is described in terms of a utility function $u(x_1, \ldots, x_n)$ or $u(x)$, maximized, subject to the budget constraint, by the equilibrium bundle $x$. The utility function is taken to be defined over $x_1 > 0, \ldots, x_n > 0$, and to have positive first-order partials, $u_j$, as well as continuous second-order partials, $u_{jk}$, everywhere in its domain of definition. Furthermore, the constrained utility maximum is assumed regular, that is, $d^2u(x)$ is negative. Less stringent conditions would suffice, but those here chosen serve to keep the exposition simple.

Let the price $p_i$ change, all other prices remaining constant. (Throughout, $i$ is arbitrary but fixed.) The price change is assumed to be accompanied by an addition of a possibly negative quantity to $x_i^0$, the initial stock of good $i$. Also, the added quantity is taken to constitute compensation, in the sense that it just enables the consumer to reattain his old utility level. Both the old and the new budget constraints are then tangent to the same indifference surface, so that the envelope theorem applies:

$$0 = \frac{\partial}{\partial p_i}(p'x - p'x^0 - m)$$

$$= x_i - \overset{0}{x_i} - p_i \frac{\partial \overset{0}{x_i}}{\partial p_i}$$

(Since there is no compensation in terms of money, $\partial m / \partial p_i = 0$.) Solving,

$$\partial \overset{0}{x_i} / \partial p_i = (x_i - \overset{0}{x_i}) / p_i \tag{1}$$

If (1) is met, the change of $p_i$ is exactly compensated.

The Slutsky equation is usually derived under the assumption that compensation is made in terms of money, often also under the assumption that the individual's initial commodity bundle is null. Different assumptions are being made here, leading to a different version of the Slutsky equation. This different version, easily found by making minor and obvious changes in any one of the familiar proofs of the Slutsky equation, is

$$\frac{\partial x_j}{\partial p_i} = \left[\frac{\partial x_j}{\partial p_i}\right]_{u=u_0} - \frac{(x_i - \overset{0}{x_i})}{p_i} \cdot \frac{\partial x_j}{\partial x_i^0}$$

In the course of the proof, $\partial x_j/\partial p_i|_{u=u_0}$ is found to be symmetric in $i$ and $j$, and negative if $i=j$. Compensation in terms of good $i$, rather than in terms of money, is thus seen to leave the usual Slutsky properties intact.

This completes the preliminaries. It will now be shown that the price of good $i$ and expenditures for good $i$ change in opposite directions, after compensation. Expenditures for good $i$ are $p_i(x_i - x_i^0)$, and

$$\left[\frac{\partial[p_i(x_i - \overset{0}{x_i})]}{\partial p_i}\right]_{u=u_0} =$$

$$\left[p_i \frac{\partial x_i}{\partial p_i} - p_i \frac{\partial \overset{0}{x_i}}{\partial p_i} + (x_i - \overset{0}{x_i})\right]_{u=u_0}$$

By (1), the right-hand side equals $p_i(\partial x_i/\partial p_i)_{u=u_0}$, which is negative. This proves the assertion.

Compensation in terms of *money* would require that a quantity $\Delta m$ be added to the consumer's initial money holdings, $m$. In the present paper, which takes compensation to be made in terms of a commodity, $\Delta m$ is zero, and $m$ is a constant. The value of this constant has played no role. Our conclusions are therefore valid also if $m=0$, and if $m\equiv 0$. The meaning of $m=0$ is clear. The identity $m\equiv 0$ holds if there exists no money in the economy. It also holds, less obviously, if money is assumed to be a (utility-bearing) commodity. In the latter case, let money be good $r$; then $p_r\equiv 1$, the budget constraint is $p'x=p'x^0$, and the conclusions derived so far are valid for all $i\neq r$. (For $i=r$, the conclusions become meaningless: $p_i$ cannot change if $p_i=p_r\equiv 1$.)

## II. Effects of an Overcompensated Price Change

If a price change is accompanied by an addition to the initial bundle so that the old equilibrium bundle becomes just reattainable, the consumer is said to be overcompensated (see Peter Newman, p. 156). The magnitude of the overcompensation can be objectively determined. Compensation, by contrast, requires that the consumer be able to tell exactly how much of an addition to his initial bundle he needs in order to be exactly as well off as before. Empirically speaking, therefore, overcompensation is preferable to compensation. On the other hand, with overcompensation there does not seem to exist an analogue of the Slutskian symmetry property, and this should perhaps be counted as a weakness of overcompensation. The weakness has its attractive side, however: if a search for the symmetry property is assumed destined to be fruitless, the conditions imposed upon the utility function may be considerably relaxed.

In this section, the utility function is taken to be strictly quasi concave and to have positive first-order partials, everywhere in the positive orthant. As before, utility is maximized subject to the budget constraint by the equilibrium bundle $x$. As before, the budget constraint is given by $p'x=p'x^0+m$.

Unlike before, we make a notational distinction between pre- and postcompensation magnitudes. The latter are marked as such by a bar: $x+dx=\bar{x}$, $x^0+dx^0=\bar{x}^0$, $p+dp=\bar{p}$, and so on. No limits are used in this section. Thus, $d$ represents differences, not differentials; differences of first- or even second-order of smallness are not considered negligible; expressions like $\partial x_j/\partial p_i$ have no meaning.

Let $p_i$ change to $p_i+dp_i=\bar{p}_i$, all other prices remaining constant. Further, let the change be accompanied by an addition $dx_i^0=(x_i-x_i^0)dp_i/\bar{p}_i$ to $x_i^0$, the initial stock of good $i$. It will first be proved that this addition constitutes overcompensation in the sense that it just enables the consumer to reattain his old equilibrium bundle.

The old equilibrium bundle satisfies the old budget constraint, or $p'x=p'x^0+m$. From the definition of $dx_i^0$ as $(x_i-x_i^0)dp_i/\bar{p}_i$ follows that $x_i dp_i=\bar{p}_i dx_i^0+x_i^0 dp_i$; adding this to $p'x=p'x^0+m$ gives $\bar{p}'x=\bar{p}'x^0+m$, showing that $x$ satisfies the new budget constraint, too. This was to be proved.

It is next shown that the Slutskian negative-definiteness property holds: $dp_i dx_i<0$. The individual, enabled by the overcompen-

sation to reattain $x$, chooses $\bar{x}=x+dx$ instead. Apparently, $\bar{x}$ was too costly before, implying

$$p'dx > 0 \tag{2}$$

(A less intuitive proof is the following. By the strict quasi concavity of the utility function, $u_1dx_1+\ldots+u_ndx_n>0$, where the marginal utilities are considered evaluated at the equilibrium bundle. By the first-order condition for a constrained utility maximum, the $u_j$ are positive multiples of the $p_j$. Combining results gives (2).) Since, furthermore, both $\bar{x}$ and $x$ satisfy the new budget constraint, one has $\bar{p}'x=\bar{p}'\bar{x}$, or $\bar{p}'dx=0$. But $\bar{p}'dx=p'dx+dp'dx$, and so, by (2), $dp'dx<0$. By assumption, $p_i$ is the only changing price. We may therefore write, equivalently,

$$dp_idx_i < 0 \tag{3}$$

This was to be shown.

Finally, it will be proved that a change of $p_i$, overcompensated in terms of good $i$, induces a change of expenditures, $p_i(x_i-x_i^0)$, in the opposite direction.

The induced expenditure change is $d[p_i(x_i-x_i^0)]$, which equals $(x_i-x_i^0)dp_i+p_id(x_i-x_i^0)+dp_id(x_i-x_i^0)$, a sum of three terms. The first term equals $\bar{p}_idx_i^0$, by the definition of overcompensation. The other two terms add to $\bar{p}_id(x_i-x_i^0)$. Altogether then, the induced expenditure change is $\bar{p}_idx_i$. Expenditures are thus seen to change in the same direction as $x_i$. By (3), that is the opposite of the direction in which $p_i$ changes. This was to be shown.

Now that an overcompensated price increase has been found to induce an expenditure decrease, it is natural to ask whether the larger of *two* overcompensated price increases will necessarily induce the larger expenditure decrease. The answer is no, as is easy to verify diagrammatically.

The conclusions of this section are, like those of Section I, independent of the value of the consumer's initial money holdings $m$. The conclusions therefore hold if $m=0$ and if $m\equiv 0$; they hold, in particular, when money is regarded as a commodity (other than good $i$).

# Liability Rules and Income Distribution in Product Liability

By Koichi Hamada*

The Coase Theorem states that under certain ideal conditions resource allocation is unaffected by liability rules. This result, however, applies only in the absence of transaction or negotiation costs. Moreover, even though resource allocation remains unaffected, the income distribution between the parties is largely influenced by the liability rule. Take the celebrated example of a confectioner and a dentist. The final level of production activity after negotiation between the parties remains the same regardless of which party is liable. But the distribution of income between the confectioner and the dentist depends crucially on which party has the right to the environment.

One of the characteristics of product liability is that producers and consumers are directly or indirectly associated through the price relationship. This very fact gives rise to a case where the conclusion of the Coase Theorem holds true even in the absence of explicit negotiations between the parties. Moreover, under certain conditions, the income distribution in terms of consumers' and producers' surplus could remain the same regardless of the liability rule.

The purpose of this paper is to explore the implication of this price relationship on the product liability. In Section I, I shall analyze the case of product liability where the probability of damage is independent of the level of care taken by producers and consumers. It will be shown in a partial equilibrium framework that not only resource allocation but also income distribution in terms of consumers' and producers' surplus is unaffected by the liability rule, provided that consumers are fully informed of the intensity and the probability of the danger. In Section II, the assumption of the independence of the probability of damage from the care level is dropped. It will be shown that the game theoretic result obtained by John Brown[1] is still valid even if the quantity to be produced and consumed is a variable.

## I. A Partial Equilibrium Analysis of the Product Liability

Let us begin with the analysis of the simplest case where there is a product, say bottled beer, which may cause damage without a safety measure. If the producer spends some additional expenditure on the product, the damage can be prevented. Moreover, we shall assume in this section that the expected value of the damage does not depend on the level of consumers' care nor any other kind of producers' care other than the expenditure on the safety measure.

Suppose the consumers consist of homogeneous individuals and their marginal utility of income can be regarded as constant. Then they are risk neutral, and we are allowed to use the apparatus of partial equilibrium analysis and the concept of consumers' and producers' surplus in a market of a single good.

In Figure 1 let $DD$ be the demand curve for a product on the condition that it is perfectly safe, and let $SS$ be the supply curve of the product without expenditure on the safety measure. Under the validity of the partial equilibrium analysis, the social gain is expressed by the social surplus, that is, the sum of the consumers' and producers' surplus. If the risks from the product, for example, due to the explosion of the bottle, can be neglected, then the maximum social surplus

* Associate professor of economics, University of Tokyo. I am much indebted to Peter Diamond and Iwao Nakajima for their helpful comments on an earlier draft of this paper.

[1] See also Diamond.

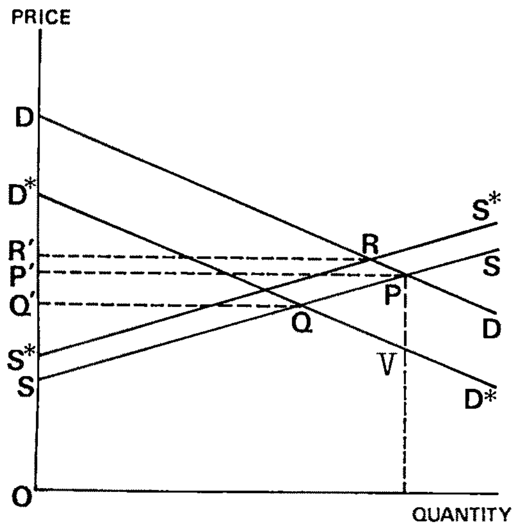

FIGURE 1

is realized as the area of triangle $DPS$ in the competitive market, $OP'$ being the competitive price.

Now we shall turn to the case where there exists danger from the product. If the expected value of the damage of explosion is $DD^*$, the demand curve for the unsafe product becomes as $D^*D^*$ if the consumers know exactly the probability of damage. Also let $SS^*$ be the cost of the safety measure for the product, so that $SS^*$ is the supply curve of the safe product inclusive of the expenditure on the safety measure.

If the producers are liable, they will compare the expected value of the compensation with the cost for implementing the safety measure. Figure 1 is drawn in such a way that $SS^*$ is smaller than $DD^*$. Accordingly, the economic calculation of the producers lets them implement the safety measure in this case because the producers' surplus is larger with the safety measure. Thus equilibrium $R$ is realized, $OR'$ being the price.

If the consumers are liable, that is, if they cannot sue the producers for the damage, it may appear that $Q$ will be realized. However, it is not so. So long as the consumers are perfectly aware of the probability and the magnitude of the damage, it is more profitable for the producers to produce the safe product because the producers' surplus $S^*RR'$ with the safe product is larger than $SQQ'$ with the unsafe product. Thus $R$ is realized in this case as well. Similarly, if $SS^*$ were larger than $DD^*$, the equilibrium corresponding to $Q$ in Figure 1 would be chosen regardless of which party be liable for the damage.

Thus regardless of the liability rule, and even in the absence of explicit negotiations, the competitive market realizes the maximization of the total surplus, provided that the victims are limited to the purchasers of the product, and that the consumers are fully aware of the expected cost of the danger. The direct or indirect price relationship between producers and consumers enables them to engage in implicit negotiations by imputing the burden of risk through the price. Moreover, the distribution between consumers' surplus and producers' surplus remains the same so long as the equilibrium is given by $R$. Thus the liability rule affects neither resource allocation nor income distribution defined in terms of consumers' and producers' surplus. This invariability of income distribution with respect to the liability rule is contrasted with the case of tort in general, where the Coase Theorem gives the invariability of resource allocation but not that of income distribution.

Thus we can state:

PROPOSITION 1: *Neither the resource allocation nor the distribution between the consumers' and the producers' surplus is affected by the liability rule, provided that the consumers are fully aware of the probability and the magnitude of the damage due to the product hazard, and that the victims are limited to the purchasers of the product.*

We should make here, however, the following reservations: First, even though the independence of distribution in terms of producers' and consumers' surplus from the liability rule implies that the *ex ante* expected cost for the damage remains the same for every consumer, it does not preclude the possibility that the *ex post*, that is, after the accident, situation of consumers may differ, depending on the rule. In the absence of a perfect insurance market, the same distribu-

tion in terms of surpluses may mean different social situations. Under caveat venditor, all the consumers pay a higher price, the victims being compensated by the producers; under caveat emptor, the consumers pay a lower price, the unfortunate victims being left uncompensated.

Secondly, the above conclusion applies only when the consumers perfectly foresee the possibility of damage. If for some reason, say, due to the newness of the product, consumers do not foresee the risk, then the demand curve does not shift by the full amount to $DD^*$. Consider the extreme case where $DD$ does not shift at all. Suppose here consumers are not allowed to sue the producers. Since consumers are unaware of the result, there is no incentive for the producers to spend on safety. Accordingly, equilibrium $P$ in Figure 1 is reached with the unsafe product. The producers' surplus equals the area of triangle $SPP'$. Consumers first conceive the consumers' surplus as equal to the area of triangle $DPP'$, but they will realize later that they have to subtract the cost of damage equal to the area of parallelogram $DD^*VP$. Of course, once consumers are fully aware of the danger, $DD$ will shift downward to $D^*D^*$ and the long-run equilibrium will turn out to be $R$. However, it is quite possible that during the transition period consumers lose parallelogram $DD^*VP$ and society loses triangle $QVP$. If the producers are liable, they will shift to the safe product as soon as they realize the danger. Thus even though the dead-weight loss $QVP$ is unavoidable even under caveat venditor so long as the producers are ignorant, the lag to the efficient response could be much shorter in this case.

Thirdly, if the victims are not the purchasers of the product as in the case of any bystanders on the explosion of a bottle, the above reasoning does not apply. Between the third party and the producers, the problem is reduced to that of the effect of the liability rule in usual tort cases such as pollution or automobile accidents. Since it is hardly conceivable that the possible bystanders are able to unite and negotiate for the possible damage, the conditions for the Coase Theorem are not satisfied, the case for caveat venditor could be stated. Of course, if the third party could sue the consumers, then the validity of Proposition 1 would be restored.

Finally, let us notice that the above result is also at least approximately applicable to the case of monopolistic suppliers. In fact, if the expected cost of damage is constant regardless of the quantity produced, $MR$ shifts downward by the amount exactly equal to $DD^*$, leaving the conclusion of Proposition 1 to hold (see Figure 2). Even though the social surplus is not maximized under any liability rule, if the producer monopolizes the market, the amount of commodity produced and the distribution of surplus between consumers and producers are unaffected by the liability rule.

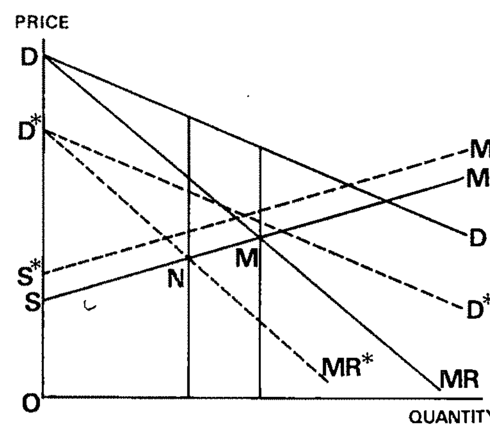

FIGURE 2

## II. The Optimal Level of Care in Product Liability

Now let us relax the assumption that the probability of accidents is independent of the level of care of consumers as well as that of producers. An accident due to a power mower, for example, depends not only on the care taken by its producer but also on the care by its operator. In his illuminating article, Brown (pp. 323 ff) analyzed the interdependence of care by the parties in the framework of a two-person noncooperative game. According to his analysis, the noncooperative solution coincides with the cooperative solution, namely, the Pareto optimal solution under a certain set of rules, pro-

vided that the required levels of care are determined by what he calls the full information incremental standard. The rules are: i) negligence; ii) strict liability with contributory negligence; iii) negligence with contributory negligence; iv) strict liability with dual contributory negligence; v) relative negligence. These rules induce both parties to act in an efficient manner if the required levels of care are set equal to the socially optimal levels.

In Brown's analysis, the question of the optimal combination of care levels is considered under the assumption of a constant level of economic activity. When one wants to apply his analysis of the accident in general to the case of product liability, the question arises whether one can discuss the problem independently of the quantity of the good to be produced and accordingly consumed.[2] Under certain assumptions to be specified below, the optimal liability rules derived by Brown's analysis will be shown to remain optimal even when the quantity produced is a variable.

Let the level of care by the producer and that by the consumer per unit of product be denoted respectively by $X$ and $Y$. They are measured in such a way that the marginal increase in $X$ and $Y$ will incur the constant cost of $W_x$ for the producer and $W_y$ for the consumer per unit of product. The magnitude of the damage per unit of the unsafe product is equal to a constant $A$.[3] The probability of the nonoccurrence of an accident per unit of product is expressed by $\pi(X, Y)$, which is an increasing function of $X$ and $Y$. That is,

$$\pi_x > 0, \qquad \pi_y > 0 \tag{1}$$

Moreover we shall assume

$$\pi_{xx} < 0, \qquad \pi_{yy} < 0, \qquad \pi_{xy} < 0 \tag{2}$$

and[4]

$$\pi_{xx}\pi_{yy} - (\pi_{xy})^2 > 0 \tag{3}$$

Let $L_x(X, Y)$ and $L_y(X, Y)$ be fractions of the damage that must be borne respectively by the producer and by the consumer. Naturally,

$$L_x(X, Y) + L_y(X, Y) = 1 \tag{4}$$

We shall list our assumptions as follows:

Assumption I: The victims of the unsafe product are limited to the buyers of product who know the probability function $\pi(X, Y)$ and the magnitude of damage $A$.

Assumption II: The marginal utility of income for the consumer can be regarded as constant, and the social benefit can be measured by the sum of producers' and consumers' surplus.

Generally speaking, the cost of extra care as well as the probability of accident may depend on the quantity of the product. But for simplicity we shall regard them as independent of the quantity of the product.

Assumption III: The unit costs of care $W_x$, $W_y$, and the probability of prevention of an accident per unit of product purchased $\pi(X, Y)$ are independent of the quantity being produced.

Let $q$ be the quantity of the product to be produced and consumed, and let $p$ be its market price. If we denote by $D(q)$ the (inverse) demand curve for the product in the absence of the possibility of an accident, then the consumers' surplus is expressed as

$$S_y(q, X, Y) = \int_0^q D(q)dq - pq - q\{W_y Y + L_y(X, Y)\,A(1 - \pi(X, Y))\} \tag{5}$$

From Assumption II the consumer is risk neutral, so that we can just deduct from the surplus the expected value of the uncompensated damage. On the other hand, let $C(q)$ be the total cost curve of the product without the cost of implementing the safety measure at all. The producers' surplus is then expressed as

$$S_x(q, X, Y) = pq - C(q) - q\{W_x X + L_x(X, Y)\,A(1 - \pi(X, Y))\} \tag{6}$$

[2] This point is discussed also by W. Y. Oi.

[3] The following qualitative result would still hold even though $A$ is a function of $X$ and $Y$.

[4] Conditions (1) and (2) are explicitly made in Brown, that is, the convexity of the isoquant is also required for the stability of his noncooperative solution. Incidentally, we follow the notation of Brown except for the probability of nonoccurrence of the accident which is denoted here by $\pi$ instead of $P$.

Accordingly, the total social surplus is

$$(7)\quad S_c(q, X, Y) = \int_0^q D(q)dq - C(q) - q\{W_xX + W_yY + A(1-\pi(X, Y))\}$$

The social optimum is achieved when the social surplus is maximized with respect to $X$, $Y$, and $q$. Define the unit cost to the producer $C_x$, the unit cost to the consumer $C_y$, and the unit social cost $C_s$ as:

$$C_x = W_xX + L_x(X, Y)A(1-\pi(X, Y))$$
$$C_y = W_yY + L_y(X, Y)A(1-\pi(X, Y))$$
$$C_s = W_xX + W_yY + A(1-\pi(X, Y))$$

It is easy to see:

*Remark*: If $q$ is given, then the social optimization (= maximization of $S_s$) is equivalent to the minimization of the unit social cost $C_s$. Similarly, if $q$ is given, then the optimization of each party (= maximization $S_x$ or $S_y$) is equivalent respectively to the minimization of the unit cost to the producer or that to the consumer.

Therefore, given $q$, the analysis of the reaction curves made by Brown is valid. The social optimum is achieved by the optimal liability rules derived by Brown, provided that the optimal value of $q$ is realized.

As long as one of the ideal rules is implemented, $X$ and $Y$ are set to the values $X_\Omega$ and $Y_\Omega$ that minimize the unit social cost. Formally, $X_\Omega$ and $Y_\Omega$ are given by $W_x = A\pi_x(X_\Omega, Y_\Omega)$ and $W_y = A\pi_y(X_\Omega, Y_\Omega)$. Here, by Assumption III, $X_\Omega$ and $Y_\Omega$ are independent of $q$, and moreover, identical for every producer and for every consumer. Let $W_xX_\Omega = \hat{\alpha}$, $W_yY_\Omega = \hat{\beta}$, and $\pi(X_\Omega, Y_\Omega) = \hat{\pi}$, then $\hat{\alpha}$, $\hat{\beta}$, and $\hat{\pi}$ are all constant and independent of $q$. Moreover, if we write $L_x(X_\Omega, Y_\Omega) = \overline{L}_x$, $L_y(X_\Omega, Y_\Omega) = \overline{L}_y$, then so long as one of Brown's optimal rules is taken, $\overline{L}_x$ and $\overline{L}_y$ do not depend on $q$ either. Therefore after optimizing with respect to $X$ and $Y$, we can write (5), (6), and (7) as follows:

$$(8)\quad S_y(q) = \int_0^q D(q)dq - pq - q\{\hat{\beta} + \overline{L}_yA(1-\hat{\pi})\}$$

$$(9)\quad S_x(q) = pq - C(q) - q\{\hat{\alpha} + \overline{L}_xA(1-\hat{\pi})\}$$

$$(10)\quad S_s(q) = \int_0^q D(q)dq - C(q) - q\{\hat{\alpha} + \hat{\beta} + A(1-\hat{\pi})\}$$

where $\overline{L}_x + \overline{L}_y = 1$.

Therefore the Pareto-efficient quantity of production $q$ is given by differentiating (10) with respect to $q$,

$$(11)\quad D(q) = C'(q) + \hat{\alpha} + \hat{\beta} + A(1-\hat{\pi})$$

On the other hand, under the perfect competition, consumers maximize (8) with respect to $q$ given $p$ leading to the demand curve:

$$(12)\quad D(q) = p + \hat{\beta} + \overline{L}_yA(1-\hat{\pi})$$

Similarly, supply curve of competitive producers is given by

$$(13)\quad p = C'(q) + \hat{\alpha} + \overline{L}_xA(1-\hat{\pi})$$

The competitive price and quantity are given by a pair $(p, q)$ satisfying (12) and (13). If we take the relation $\overline{L}_x + \overline{L}_y = 1$ into consideration, we can derive (11) from (12) and (13). Thus we have seen that the competitive solution under care levels $X_\Omega$ and $Y_\Omega$ achieves also the Pareto-efficient quantity of production. That is, the care levels $X_\Omega$, $Y_\Omega$, and accordingly the liability rules that are derived as optimum without reference to the level of quantity produced are socially optimal even if the level of economic activity itself is a variable.

Generally speaking $\overline{L}_x$ and $\overline{L}_y$ differ depending on a particular rule among the ideal liability rules. But it is clear from (11) that the values of $\overline{L}_x$ and $\overline{L}_y$ do not affect the value of $q$. Nor do they affect $S_y$ or $S_x$. For by substituting (12) into (8), and (13) into (9), one obtains

$$(14)\quad S_y = \int_0^q D(q)dq - qD(q)$$

$$(15)\quad S_x = qC'(q) - C(q)$$

PROPOSITION 2: *If perfect competition pre-*

*vails under Assumptions I, II, and III, the rules for minimizing the unit social cost also maximize the total social surplus. Neither the level of production (consumption) nor the distribution of surplus between consumers and producers is affected by the liability rule.*

This proposition is a generalization of the analysis of the optimum combination of the levels of care to the case of product liability, and at the same time a generalization of the discussion in the last section that the division of surplus is independent of the liability rule in the context of product liability when the probability of damage and its magnitude are completely foreseen. If the supplier is a monopolist, then the socially optimal quantity is not produced. But the neutrality of the division of surplus between the consumers and the producers with respect to the liability rule still holds.

Let us relax Assumption III and let $W_x$, $W_y$ depend on the amount of production or consumption. In fact, for example, when there are economies of scale in preventing danger—that is, the greater the production, the less costly to produce a safe product—marginal cost of care $W_x$ is a decreasing function of the amount of production or consumption. If the cost of care to an individual producer depends on the amount of his *own* production, and if the cost of care to an individual consumer depends on the amount of his *own* consumption, then the same conclusion as in Proposition 2 will hold true under the following additional assumptions:

Assumption IV: All the producers are identical; all the consumers are identical.

Assumption V: $W_x$ and $W_y$ depend on $q$. But $D(q)-W_y(q)-A(1-\pi(X, Y))$ is a decreasing function of $q$, and $C'(q)+W_x(q)+A(1-\pi(X, Y))$ an increasing function of $q$. Then we can state:

PROPOSITION 3: *If perfect competition prevails under Assumptions I, II, IV, and V, the rules for minimizing the unit social cost also maximize the total social surplus. Neither the level of production (consumption) nor the distribution of surplus between consumers and producers is affected by the liability rule, so long as the society sticks to a single rule.*

Assumption IV is necessary in order to analyze the situation in terms of the representative producer and the representative consumer. Assumption V is required to ensure the second-order condition. The proof goes in a similar manner as that of Proposition 2, utilizing the remark stated there, so that it will be omitted here.[5]

One cannot help feeling uneasy about the above results because the court has to know in advance the socially optimal level of care in order to determine the care standard. In the case of product liability, however, there is a direct or indirect relationship between the consumers and the producers, which enables both parties to engage in implicit negotiations through price. This raises the question whether in some ideal situations the price mechanism itself could achieve the efficient combination of care levels as well as the efficient amount of production without any care standard.

Define the *uninsured price* as

$$p^* = p - L_x A(1 - \pi(X, Y))$$

and the *risk-free price* as

$$p^+ = p + L_y A(1 - \pi(X, Y))$$

The uninsured (supply) price is the price that would prevail if the producer were not liable, and the risk-free (demand) price is the price that would prevail if the consumer were free of any damage. Ultra-considerate or ultra-rational consumers may take the uninsured price as given, and ultra-considerate or ultra-rational producers may take the risk-free price as given in each case instead of the market price. Under these extremely hypothetical assumptions, one can prove the efficiency of price systems without any prescribed care standard, and also the neutrality of the liability rule on the distribution of the

[5] The main difference is that the optimal levels of care $(X_\Omega, Y_\Omega)$ are no longer independent of $q$ but are functions of $q$. But if we notice that $\bar{L}_x$ and $\bar{L}_y$ are independent of $q$ so long as a single rule among the ideal rules is adopted, we can prove the proposition almost in the same way as we proved Proposition 2.

social surplus. Needless to say, this last remark should be interpreted not as the manifestation of the feasibility of the complete market deterrence, but as the indication of the unrealistic and restrictive nature of the assumptions that are required for its feasibility.

# The Social Cost of Input Distortions: A Comment and a Generalization

By JAMES E. ANDERSON*

Daniel Wisecarver and Richard Schmalensee in two recent papers on the social cost of input market distortions have committed a rather interesting error. They find a different measure of welfare loss due to an input price distortion depending upon whether the measure is in the output or input market. This is incorrect, as intuition surely argues, and the source of the error lies in improper use of the Taylor's series expansion. Correcting the error suggests a worthwhile generalization.

## I. The Error

The error is clearest in the case, considered by both, of price change in a single input used exclusively to produce a single output in competitive partial equilibrium. I first set out the correct analysis. Output $X$ is produced by a degree one homogeneous function of labor $L$ and land $R$, both available in infinitely elastic supply at rates $w_0$ and $r_0$, respectively. Labor is subsidized at rate $\Delta w/w_0$ and the welfare loss is to be computed. Let $a_L \equiv L/X$, $a_R \equiv R/X$. For a degree one homogeneous function, the $a_i$ are functions solely of $w$, $r$: $a_L = a_L(w, r_0)$, $a_R = a_R(w, r_0)$. Then we may use the identity to obtain input demand functions: $L = Xa_L(w, r_0)$, $R = Xa_R(w, r_0)$. In competitive equilibrium with positive production there are no profits, so that $P = a_L w + a_R r_0$, where $P$ is the price of output. Furthermore, by the envelope theorem (unit cost minimization), $w da_L + r da_R = 0$ and thus $\partial P/\partial w = a_L$. All output is sold, so that the output $X = C(P)$, where $C$ is consumption. Measuring the welfare change exclusive of the subsidy payment in the input market yields

$$\Delta S = \int_{w_0}^{w_1} X(P(w))a_L(w)dw$$

Substituting

$(\partial P/\partial w)\cdot dw = a_L(w)dw = dP(w)$, we have

$$\Delta S = \int_{P(w_0)}^{P(w_1)} X(P(w))dP(w)$$

which is the measure of change in the output market. Net welfare changes by $\Delta S + \Delta G$ where[1] $\Delta G = (w_1 - w_0)a_L(w_1)X(P(w_1)) = (w_1 - w_0)L_1$.

How do Wisecarver and Schmalensee obtain different measures? By failing to change $w$ in the output measure to a consistent order of expansion with $w$ in the input market measure. Consider the quadratic approximation in the input market:

$$\begin{aligned}\Delta S &= L(w_0)dw + \frac{1}{2}\frac{\partial L}{\partial w}(w_0)dw^2 \\ &= a_L(w_0)X(P(w_0))dw \\ &\quad + \frac{1}{2}X(P(w_0))\frac{\partial a_L}{\partial w}(w_0)dw^2 \\ &\quad + \frac{1}{2}\frac{dX}{dP}(P(w_0))a_L^2(w_0)dw^2\end{aligned}$$

This translates into the output market as:

$$\begin{aligned}\Delta S &= X(P(w_0))d_2P(w) \\ &\quad + \frac{1}{2}\frac{dX}{dP}(P(w_0))[d_1P(w)]^2\end{aligned}$$

where $d_2P(w)$ denotes the second-order approximation to the change in $P(w)$ and $d_1P(w)$ denotes the first-order approximation to the change in $P(w)$.

* Associate professor of economics, Boston College. I am indebted to J. Huston McCulloch and a referee for helpful comments. I also benefited from conversations with Michael Klass concerning a related paper he coauthored with Alan Deardorff.

[1] Note that $L_1(w_1 - w_0) \neq X(P(w_1))[P(w_1) - P(w_0)]$ in general.

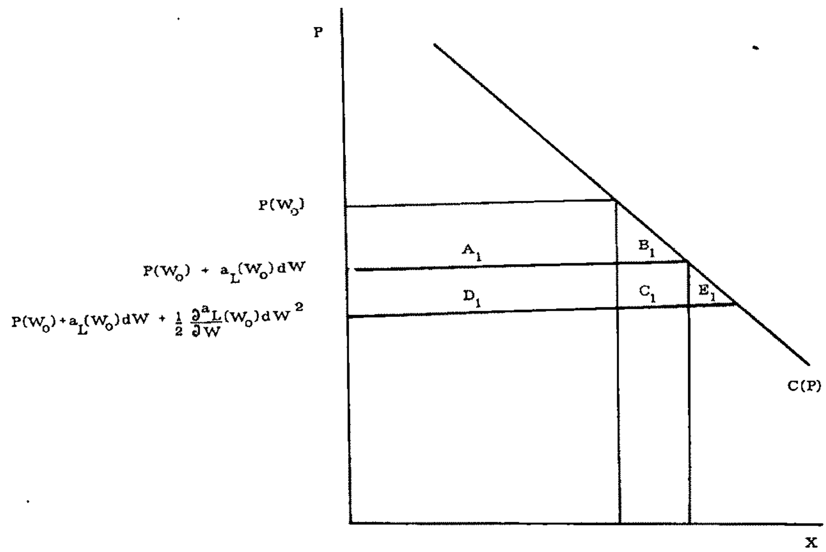

FIGURE 1

In terms of Figure 1, $\Delta S = A_1+B_1+D_1$. Schmalensee argues that $A_1+B_1$ is the correct measure of the change in surplus, while Wisecarver argues for $A_1+B_1+D_1$. Schmalensee's $A_1+B_1$ is not a correct measure under any circumstances. Wisecarver's measure is the true quadratic approximation (in $dw$) in either market. His participation in the error lies in failing to see the source of the problem and accepting Schmalensee's finding that input and output market measures are different. The confusion over consistent expansion can also be seen in higher order terms. Suppose the change in surplus is measured in Figure 1 to the second order in $dP(w)$. The areas $C_1$ and $E_1$ are added to $\Delta S$. They are third and fourth powers of $dw$, but do *not* represent the true third- and fourth-order approximation terms. Measuring $\Delta S$ as $A_1+B_1+C_1+D_1+E_1$ would essentially repeat Schmalensee's error. The Taylor's series approximation always gives the same answer in input and output markets provided it is used to a consistent order of expansion.

A further diagrammatic analysis may be instructive. In Figure 2, land is used as a numéraire ($r_0=1$). As shown $ff'$ is the initial budget line and is tangent to $X_0$ at the initial production point. In terms of land, total cost of $X_0$ is $Of$. The wage decrease causes a shift in cost at constant employment of factors to $Oe$; the difference being $fe$. The value of labor employed in the initial situation is $hf$, and after the tax $he$; the difference again being $fe$. With substitution occurring, the difference rises to $fd$.[2] This demonstrates that in both markets with $dC/dP=0$ $(dX=0)$, the welfare change in either market exclusive of subsidy payment is $\Delta S = fd$. Any consistent degree of approximation of $\Delta S$ must obtain the same measure in either market.

Now consider $X_0$ changing to $X_1$. For simplicity, assume $C$ is linear in $P$. In this case we have:

$$\begin{aligned}\Delta S &= X_0\Delta P + \tfrac{1}{2}(X_1 - X_0)\Delta P \\ &= \tfrac{1}{2}X_0\Delta P + \tfrac{1}{2}X_1\Delta P\end{aligned}$$

Allowing substitution to occur, we obtain:

$$\Delta S = \tfrac{1}{2}fd + \tfrac{1}{2}ab$$

$$\Delta S + \Delta G = \tfrac{1}{2}(fd + ab) - ac$$

This measure is also the net loss in the labor market. If $L(w) = X(P(w))a_L(w)$ is forced to be linear in $w$, a mistake made by both au-

[2] For the labor market, $fd$ is the familiar Hicksian compensating variation measure.

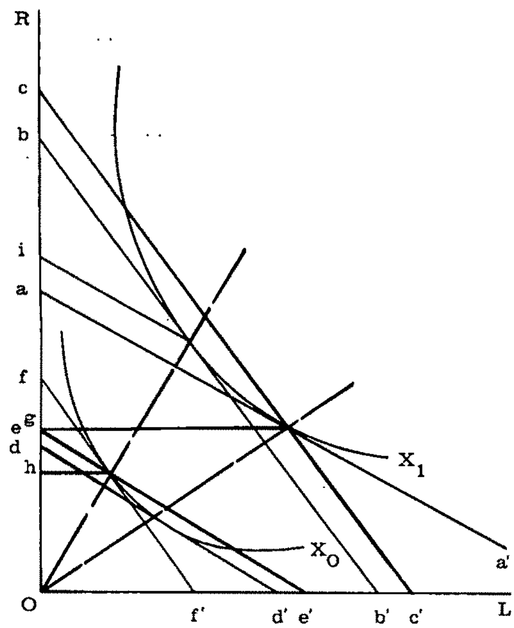

FIGURE 2

thors, we obtain an erroneous different answer.

$$\begin{aligned}\Delta S' &= L_0\Delta w + \tfrac{1}{2}(L_1 - L_0)\Delta w\\ &= \tfrac{1}{2}L_0\Delta w + \tfrac{1}{2}L_1\Delta w\\ &= \tfrac{1}{2}(fe + ac)\\ \Delta S' + \Delta G &= \tfrac{1}{2}(fe + ac) - ac = \tfrac{1}{2}fe - \tfrac{1}{2}ac\\ &= (\Delta S + \Delta G) - \tfrac{1}{2}(ed - bc)\end{aligned}$$

Note that $bc > ed$ in general (given degree one homogeneity and downward sloping final demand). Therefore the input market approximation understates the loss.

The lesson in these mistakes is that quadratic approximations must be used carefully, and perhaps that where theoretical doubts exist, integration should be used.

## II. A Generalization

Studying the correct solution to the error above suggests a generalization. We have seen that: $L(w) = a_L(w)X(P(w)) = X(P(w)) \cdot \partial P/\partial w$. The derivative of the expenditure function (the rate of change of the compensating variation) with respect to the price of labor is precisely the demand for labor. This is quite generally true. Let $S = \sum_i P_iC_i$ be the consumer's expenditure, $(P_1, \ldots, P_n) = P$ be the commodity prices, $(w_1, \ldots, w_m) = w$ be the input prices, and $R_1, \ldots, R_m$ be the factor demands. Make the one-person economy assumption and consider the consequence of changing any factor price.

$$\frac{\partial S}{\partial w_j} = \sum_i \frac{\partial S}{\partial P_i}\frac{\partial P_i}{\partial w_j}$$

With utility held constant,

$$\frac{\partial S}{\partial P_i} = C_i + \sum_k P_k \left.\frac{\partial C_k}{\partial P_i}\right|_{comp} = C_i(P)$$

Then

$$\frac{\partial S}{\partial w_j} = \sum_i C_i \frac{\partial P_i}{\partial w_j} = \sum_i C_i a_{ij} = R_j(w)$$

In measuring the welfare consequences of a factor price change we can integrate either with compensated output demands or with compensated factor demands.[3]

The latter measure involves compensating variations on *factor indifference* curves. These were invented by N. F. Laing for the 2x2 general equilibrium model some years ago. Each such curve gives the locus of factor endowment points which enable utility to be at the given level provided the economy operates with technical efficiency (marginal value products = factor prices and marginal costs = commodity prices). The set of factor indifference curves give (ordinal) utility as a function of endowments. It can be shown that this is a quasi-concave function (Laing has a geometric proof for the 2x2 case).

The geometry may suggest an economy of effort in welfare measurement. Suppose the impact of a vector of factor price changes is to be evaluated. If there are many more factors than goods it may pay to estimate the implied commodity price changes (shifts in unit cost) and then measure the compen-

[3] Note that the symmetry condition holds for the compensated factor demands. This ensures the path independence of the line integral used to evaluate $\Delta S$. Some paths correspond to evaluation over output demands while others correspond to evaluation over input demands.

sating variation by moving a budget plane around an indifference curve in commodity space. On the other hand, with more goods than factors it may pay to aggregate factor demands and measure the compensating variation by moving a budget plane around an indifference curve in factor space.

In practice this discussion suffers from the defects of all surplus analysis—it assumes equilibrium prices are somehow known without solving the general equilibrium problem and it ignores the serious difficulty in inferring aggregate compensating variations from aggregate data.[4] One's reaction to these defects is apparently a matter of taste, but even at a theoretical level there is an appealing convenience to reducing the dimensionality of the compensating variation measure.

[4] For a good discussion, see Donald Richter.

# Another Look at the Social Valuation of Input Price Changes

By RICHARD SCHMALENSEE*

In an earlier paper in this *Review*, I considered the Marshallian consumer's surplus valuation of changes in the private and social cost of an intermediate good used by a competitive industry that produced a consumer good under constant returns to scale.[1] I noted that Marshallian measures of the dollar values of such changes could be computed in either the input or final product market and argued that the results would differ unless no substitution were possible in the production of the final good. I concluded that, since the input market can at best reflect the consumer's surplus generated in the final product market, the measure computed in the latter should be used.

Recently, Daniel Wisecarver described this conclusion as "faulty" and "incorrect." Wisecarver was concerned with the social cost of a tax on (or other distortion affecting the market for) an input used in the production of a consumer good; he retained the assumptions of competition and constant returns. He too found that the input and product market valuations would generally differ, but he presented cogent arguments for the superiority of the former measure.

Since Wisecarver did not attempt to exhibit my errors, and since the situations we considered were different, I first suspected that as often happens in economics, we were both right, but about different things. A reexamination of the question, however, did not support this suspicion. We were in fact both wrong and about the same thing. In both situations, the Marshallian valuations computed in the input and product markets are identical. Under competition, either measure can thus be used in practice; the choice between them can properly be made on the basis of convenience.

The following section proves this assertion for a model which contains the two earlier papers as special cases, and it indicates where Wisecarver and I went astray. Section II reexamines a related question considered in my earlier paper: the valuation of input price changes when sellers of the final product have monopoly power.

Let $Q$ be the amount of the final product produced, let $P$ and $MR$ be the corresponding price and marginal revenue, and let $(X_1, \ldots, X_n)$ be the vector of the quantities of the $n$ inputs employed in production.[2] Let $(r_1, r_2, \ldots, r_n)$ be the vector of private and social marginal costs of these inputs. It is assumed throughout the formal analysis that all inputs are in perfectly elastic supply and that $(r_2, \ldots, r_n)$ are fixed, so that we can write $r$ for $r_1$ and $X$ for $X_1$. It is assumed throughout that all the $X_i$ are positive, and the production function for $Q$ is assumed well behaved.

Let $TC(Q, r_1, \ldots, r_n)$ be the minimum private cost of producing output $Q$ with fixed private input prices $(r_1, \ldots, r_n)$, and let $MC(Q, r_1, \ldots, r_n)$ be the corresponding marginal cost function. If the underlying production function is homogeneous of degree $h$, it is easy to show that $TC$ may be written as

$$(1) \quad TC(Q, r_1, \ldots, r_n) = Q^{1/h} G(r_1, \ldots, r_n)$$

where $G$ is concave, nondecreasing, and increasing in $r_1$. Finally, Shephard's lemma implies that the cost-minimizing input demands are given by[3]

$$(2) \quad X_i(Q, r_1, \ldots, r_n) = \partial TC(Q, r_1, \ldots, r_n)/\partial r_i, \quad i = 1, \ldots, n$$

* Associate professor of economics, University of California, San Diego. I would like to thank, with the usual disclaimer, Elizabeth Bailey, George Borts, R. Robert Russell, and Robert Willig.

[1] For an interesting recent discussion of the Marshallian measure, see Willig.

[2] This essay thus relaxes Wisecarver's assumption that $n=2$.

[3] See, for instance, W. E. Diewert, pp. 595–96.

The following two sections consider the social valuation of a change in the social cost of the first input from $r_1$ to $(r_1+\alpha t)$, accompanied by a change in the private cost from $r_1$ to $(r_1+t)$. In Wisecarver's analysis, $\alpha$ was zero, and $t$ was positive, since he was concerned with the impact of taxes or other distortions. My earlier paper was concerned with government actions like research and development projects that would lower both costs equally, so I assumed $\alpha=1$ and $t<0$. A variety of other assumptions are possible. A government investment that lowered the cost of irrigation water and was amortized by pricing the water above marginal cost, for instance, would involve $\alpha>1$ and $t<0$.

Regardless of conditions in the final product market, the Marshallian surplus that would be measured in the market for the first input can be written as

$$(3) \quad S_i(t) = \int_0^{X(t)} \rho(x)dx - (r+\alpha t)[X(t)]$$

where $X(t)$ is the amount of the first input used when its cost is $(r+t)$, and $\rho(x)$ is the inverse demand curve for the first input.[4] The value $S_i(t)$ is simply the usual area under the (input) demand curve, minus the social cost of the (input) quantity actually demanded. The functions $X(t)$ and $\rho(x)$ depend on technology, demand, and behavior in the final product market. Differentiation of (3) yields

$$(4) \quad dS_i(t)/dt = -\alpha X(t) + (1-\alpha)[dX(t)/dt]t$$

The social valuation of the change in $t$ described above that would be computed in the input market is given by

$$(5) \quad V_i(t) = S_i(t) - S_i(0) = \int_0^t [dS_i(\tau)/d\tau]d\tau.$$

[4] That is, $\rho[X(t)]=(r+t)$. If this integral, or the one defined by (7), fails to exist because of the behavior of the inverse demand function near zero, the lower limit of integration may simply be changed to some small positive number, without affecting anything that follows.

For small $t$, the first two terms of the Taylor series expansion about $t=0$ can be used to approximate this quantity:

$$(6) \quad V_i(t) \simeq E_i(t) = t[dS_i(0)/dt] + (t^2/2)[d^2S_i(0)/dt^2]$$

In the final product market, on the other hand, the net Marshallian surplus as a function of $t$ can be written as

$$(7) \quad S_f(t) = \int_0^{Q(t)} P(q)dq - (r+\alpha t)[X(t)] - \sum_{i=2}^{n} r_i X_i(t)$$

This is simply the area under the demand curve minus the social cost of production. Note that factor demands are based on private cost, while inputs are valued at their social costs. The functions $Q(t)$ and $X_1(t) \ldots X_n(t)$ again depend on technology, demand, and behavior in the final product market. An analyst working in the final product market would attempt to measure as accurately as possible the change in $S_f$ caused by a change in $t$. If the Marshallian approach is accepted, it seems obvious that this change is the correct measure of the social value of changes in $t$. Differentiation of (7) yields

$$(8) \quad dS_f(t)/dt = P[dQ(t)/dt] - (r+\alpha t)[dX(t)/dt] - \sum_{i=2}^{n} r_i[dX_i(t)/dt] - \alpha X(t)$$

The quantities $V_f(t)$ and $E_f(t)$ are defined by the obvious analogs of (6) and (7).

## I. Competition

In this section and the next, equilibrium final good output and input demands depend on $t$ only through its effect on the private cost of the first input since production is assumed to minimize private cost, and the private costs of all other inputs and the demand and production functions are assumed fixed. Thus the derivatives of the input demand functions appearing in (4) and (8) are given by

$$(9)\quad dX_i/dt = dX_i/dr = (\partial X_i/\partial Q)(dQ/dr) + (\partial X_i/\partial r),\ i = 1, \ldots, n$$

where the partial derivatives on the right are those of the input demand functions in (2). Similarly, $dQ/dt = dQ/dr$.

Using the superscript $c$ to denote the competitive case, we first prove that $V_i^c(t) = V_f^c(t)$ for any $t$ by showing that $dS_i^c/dt$ and $dS_i^c/dt$ are identically equal for all $t$. If $MP_i$ is the marginal physical product of input $i$, differentiation of the production function for the final product with respect to $r$ yields

$$(10)\quad dQ/dr = \sum_{i=1}^{n} MP_i(dX_i/dr) = \left[(r+t)(dX/dr) + \sum_{i=2}^{n} r_i(dX_i/dr)\right] \Big/ MC$$

where the last equality follows from the private efficiency of production. Under competition $P = MC$ so that substitution for the summation in (8) from (10) yields immediately

$$(11)\quad dS_f^c(t)/dt = -\alpha X + (1-\alpha)(dX/dr)t \equiv dS_i^c(t)/dt$$

from (4), and the proof is complete. Note that it required only private efficiency of production and marginal cost pricing. In particular, it did not require the assumption of linear homogeneity that both Wisecarver and I made in our earlier work. It should also be noted that since it has just been proven that $V_i^c(t) = V_f^c(t)$ for any $t$, it follows that analysis of the two markets will yield precisely the same results even for large $t$.

How then did Wisecarver and I conclude that for small $t$ these measures generally differed by a term in $t^2$? To answer this, let us first differentiate (11) and form the Taylor approximation

$$(12)\quad E_i^c(t) = E_f^c(t) = \alpha Xt - (t^2/2)(1-2\alpha)(dX/dr)$$

where both $X$ and $(dX/dr)$ are evaluated at $t=0$. Under the assumption of linear homogeneity, (1) holds with $h=1$. This implies that $G = MC$,

$$(13)\quad X = Q(\partial G/\partial r) = Q(\partial MC/\partial r)$$

and

$$(14)\quad dX/dr = (dQ/dr)(\partial G/\partial r) + Q(\partial^2 G/\partial r^2) = (dQ/dP)(\partial MC/\partial r)^2 + Q(\partial^2 MC/\partial r^2)$$

using the assumption of marginal cost pricing. Substituting into (12), we have

$$(15)\quad E_i^c(t) = E_f^c(t) = Q(\partial MC/\partial r)t - (1-\alpha)Xt - [(1-2\alpha)/2] \cdot [(dQ/dP)(\partial MC/\partial r)^2]t^2 + [(1-2\alpha)/2] \cdot [Q(\partial^2 MC/\partial r^2)]t^2$$

Both Wisecarver and I used (12) to define $E_i^c$. We used something like (15) to define $E_f^c$, but since we both considered only a first-order approximation to the change in marginal cost, we omitted the final term on the right.[5] Under fixed coefficients, $\partial^2 MC/\partial r^2$ is zero, and we correctly concluded that the two approximations were equal in this case. But when substitution is possible, this quantity is negative, so that its omission from our expressions for $E_f^c$ led us to the conclusion that this quantity was not equal to $E_i^c$ unless substitution was impossible. This conclusion, to repeat, is wrong; it was shown above that under competition, identical measures of the surplus change will be obtained in the affected input market and in the final product market even for substantial changes in input prices and costs.

## II. Monopoly Power

We will use the superscript $m$ to denote the case where the final product is produced by firms with monopoly power. Equation (10) can be used to simplify the expression for $dS^m/dt$ as before, but the substitution

[5] Compare my equation (3) and Wisecarver's equation (4).

$P=MC$ cannot be made. Instead, equations (4), (8), and (10) yield

$$(16)\quad dS_i^m/dt = dS_f^m/dt - (P - MC)(dQ/dr)$$

Assuming the first input is not inferior, $(dQ/dr)$ is negative as long as marginal revenue is declining, and it follows that $dS_i^m/dt$ is greater than $dS_f^m/dt$, the true measure of surplus change. Since an increase in $t$ must serve to lower consumer's surplus, $dS_f^m/dt$ is negative. It then follows that both the social costs of increases in $t$ and the social gain from decreases in this quantity will be underestimated by analysis of the input market.

The basic reason for this bias is simple. Under perfect competition, the net Marshallian surplus $S$ is maximized for given input prices by marginal cost pricing of the final product, so that the partial derivative of $S$ with respect to output is zero. Under imperfect competition, however, this partial derivative is positive since the community as a whole would benefit from increased output. But the welfare effect of *ceteris paribus* output changes is not reflected in input demand functions, and it thus cannot be detected by analysis of input markets.[6]

Things are clearest under the assumption of pure monopoly, which implies $MC=MR$. A monopolist's input demand functions are exactly those of a competitive industry with the same technology and a demand curve equal to the monopolist's marginal revenue schedule. Thus the monopolist's input demands, which depend on marginal revenue products, in effect value changes in final output at $MR$, while the community as a whole values them at $P$. There is simply no way for the $(P-MR)$ difference to show up in analysis of input markets.

One way to salvage input market analysis in this case suggests itself. It might seem that if one knew that the input were sold to a pure monopolist, this knowledge could be used along with additional information to correct the input market valuation of a change in $t$. In fact this can be done for small $t$, but the additional information needed is considerable.

To see this, let $FE_i^m$ and $FE_f^m$ be the first terms in the Taylor approximatious $E_i^m$ and $E_f^m$. To compare these first approximations, first note that under pure monopoly

$$(17)\quad dQ/dr = (dQ/dMR)(dMC/dr) = (dQ/dMR)[(\partial MC/\partial Q)(dQ/dr) + (\partial MC/\partial r)]$$

Second, for any inverse demand function $P=P(Q)$

$$(18)\quad dMR/dQ = 2(dP/dQ) + Q(d^2P/dQ^2)$$

Finally, if the monopoly's production function is homogeneous of degree $h$, equation (1) yields

$$(19)\quad \partial MC/\partial r = X/hQ,$$

$$(20)\quad \partial MC/\partial Q = (1-h)MC/hQ$$

Solving (17) and substituting from (18)–(20), it follows that for a pure monopoly with a homogeneous production function

$$(21)\quad dQ/dr = -XE/PZ$$

where $E$ is the absolute value of the price elasticity of demand

$$(22)\quad Z = h(2-W) + (1-h)(E-1)$$

$$(23)\quad W = (EQ^2/P)(d^2P/dQ^2)$$

It is easy to show that $W$ is less than two if marginal revenue is declining and that the second-order condition for monopoly equilibrium requires $Z$ to be positive.

Equations (4), (6), (16), and (21) along with the first-order conditions for monopoly equilibrium serve to establish the appropriate correction:[7]

$$(24)\quad FE_f^m = FE_i^m[1 + (1/\alpha Z)]$$

where $Z$ is evaluated at $t=0$. First note that if $\alpha$ is zero, no loss is estimated in the input market if terms involving $t^2$ are neglected. In this case, (24) cannot be used and there is no alternative to analysis of the final product

[6] Effects of this sort are briefly discussed in Wisecarver's Section III.

[7] Equation (24) generalizes equation (12) of my earlier paper.

market. Second, even if $\alpha$ is positive, and even in the very special case where $h$ is known to be unity, $W$ must be estimated in order to estimate $Z$. Since $Z$ equals two when final demand is linear under these assumptions, while it equals $(2E-1)/E$ when $E$ is constant, it is clear that one must be quite certain of the form of the final demand function to estimate this quantity with any precision.

Things become even more complicated if a second-order approximation is required. Under the homogeneity assumption, differentiation of (16) and use of (1) and (19)–(21) yields

$$(25)\quad E_f^m = E_i^m - (X/Z)t - (1/2Z)(\partial MC/\partial r)(dQ/dr)t^2 - (hQ/2Z)(\partial^2 MC/\partial r^2)t^2 + (X/2Z^2)(dZ/dr)t^2$$

The second and third terms on the right of this expression are nonzero in general, and they involve the difficult-to-estimate quantity $Z$. The fourth term, which also involves $Z$, is zero if and only if input ratios are fixed by technology. From (22) and (23), the final term vanishes if $E$ is constant along the demand curve, or if demand is linear and $h=1$. In general, from (23), it will involve the third derivative of the inverse demand function.

# IN MEMORIAM

## JOSEPH STANCLIFFE DAVIS

### 1885–1975

Joseph S. Davis, Emeritus Professor of Economic Research and former Director of the Food Research Institute of Stanford University, died in Los Altos, California, on April 23, 1975, at the age of 89. He served as president of the American Economic Association in 1944.

Joseph Davis was born on a small farm in Chester County, Pennsylvania, on November 5, 1885. He graduated from Harvard University summa cum laude in 1908 and was awarded the Doctorate of Philosophy in 1913. He served as a member of the Harvard faculty from 1913 to 1921, with an interruption for service on the Allied Maritime Transport Council in London in 1918–19. In July 1921, he was appointed as one of the three original directors of the Food Research Institute at Stanford University. That Institute was his primary concern until he became emeritus in 1952.

The years from 1921 to 1952 were ones of great achievement in scholarship and institution building. In 1970 Davis recounted how he and the other two directors set out to build an "accurate and increasingly comprehensive body of significant knowledge on world food production, distribution, and consumption." They took as their goals "to analyze, objectively, issues of public policy, and to express the findings clearly and forthrightly, orally and in print." The results of much of this research were embodied in twenty volumes of *Wheat Studies* that were published from 1925 to 1944; they contain twelve special studies and thirty-one survey and review issues of which Davis was author or coauthor, despite the fact that he was away from the university for extended periods in government service. There were also books and very many professional papers. His first book *Essays in the Early History of American Corporation* was published in 1917; his last, *The World Between the Wars*, was published in 1975.

Various of Davis's published essays are landmarks. In August 1949 he presented a paper to the Farm Economic Association at Laramie, Wyoming, entitled "Our Amazing Population Upsurge," that was the opening salvo in his attack on accepted projections of the population of the United States, an attack that ended the interwar belief in a static American population. That paper resulted from his thoroughness in research, his insistence on having the latest information, and his reluctance to trust standing estimates or received doctrine. He had been working for some time on a book on consumption economics, and as he reviewed population projections for the United States and compared them with current population figures he began to sense that something was wrong. As he probed more deeply into the matter, the book was set aside and he concentrated almost exclusively on the population question; it continued to be a matter of special interest into the 1960s.

An article of September 1934, entitled "Agricultural Fundamentalism," is a superb exposition and critique of beliefs then widely held—and still held in some circles—about the place of agriculture in national economies; and it is a model essay, balanced, thoughtful, informed, and lucid.

A third article was published in July 1932 and is particularly apt today. It was entitled "The Specter of Dearth of Food: History's Answer to Sir William Crookes." (It is not, of course, the only article that Davis wrote on this general subject. A particularly cogent statement on the same subject was "Adam Smith and the Human Stomach" in 1954.) Crookes was one of the most eminent scientists of his generation, and in his presidential address to the British Association for the Advancement of Science in 1898 he had forecast a crisis in world food supplies by 1931. Davis carefully examined all of the elements of Crookes's argument and

the quality of his information as a way of getting a better understanding of why the forecast had been so wrong and how better forecasts might be made. He concluded that "political and social factors, not natural or economic limitations, are the principal obstacles to continuous advance in the plane of living."

From his earliest years as an economist, Davis was able to combine scholarly research of the highest quality with the strenuous demands of public service. In 1918–19 he served as an assistant statistician for the American Shipping Mission to London and also as statistician for the Allied Maritime Transport Council. He was a member of the staff of the Dawes Commission on Reparations in 1924, a member of a team studying the Fiscal and Economic Position of Mexico in 1928, chief economist of the Federal Farm Board in 1929 to 1931, a member of the Food and Nutrition Board of the National Research Council from 1940 to 1945, and of the Institute of Pacific Relations from 1941 to 1947. In 1955, three years after his official retirement, he was called to serve for nearly four years as a member of President Eisenhower's Council of Economic Advisors.

The years were also not without their honors. In addition to being president of this association, Davis was elected president of both the American Statistical Association and the American Farm Economic Association in 1936, and in 1957 he was made one of the first Fellows of the American Farm Economic Association. But he cherished just as much the "Distinguished Alumnus Award" he received in 1973 from Westchester (Pa.) State College, where he graduated in 1902.

Davis used to say that he felt more at home in research than in teaching, and that he had no real gift for classroom teaching. He did in fact have a great gift for teaching, by a word here, a sharp question there, a turn of phrase, or an aphorism. And many young scholars found his probing interest in their research the finest reward they could wish for and the greatest possible stimulus to their best efforts. At the same time, he rarely engaged in small talk, and those who did not know him were sometimes taken aback by the abruptness with which business conversations began and ended.

Joseph Davis was a teacher as well as a devoted seeker of knowledge and a loyal servant of his society. As he taught himself, he taught others, and his persistent emphasis on "expressing findings clearly and forthrightly" was an essential element in this teaching. He never lost his desire to know, and he was indomitable in overcoming ignorance. In a talk to a Stanford undergraduate group in 1961 he said "Life has been far tougher, but much richer, than I dimly anticipated when I was twenty." He would surely have said the same thing fourteen years later.

# NOTES

Economists who are *strongly* oriented toward the humanities, who use humanistic methods in their research, and who will be participating in meetings abroad that are concerned with the humanistic aspects of their discipline are eligible to apply for travel grants of the American Council of Learned Societies. Specifically, economists may be eligible if (a) they deal with the history of economic thought or economic history, and (b) if their approach is qualitative and descriptive rather than quantitative and statistical. Conferences dealing with the establishment of social policy or legislation are generally ineligible. The deadlines for applications to be received in the office of the American Economic Association are: for meetings scheduled between June and September, February 15; for meetings scheduled between October and January, June 15; for meetings scheduled between February and May, October 15. Application forms may be obtained from C. Elton Hinshaw, Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

---

Nicolaus and Associates have been appointed the official travel coordinator for the Atlantic City meetings of Allied Social Science Associations. Group air fares may be arranged from your city and for groups as small as fifteen. These fares usually run about 25 percent below regular coach fare. Some examples using current fares subject to change are:

| Round Trip: | Coach | Group |
|---|---|---|
| New York-Atlantic City | $ 61.46 | $ 41.46 |
| Detroit-Atlantic City | 161.46 | 87.46 |
| San Francisco-Atlantic City | 389.46 | 310.46 |

Flights will be arranged for other cities if enough individuals show interest. Air reservation forms and general information on flights and costs will be mailed to you in April with the preregistration material. In the meantime if you have any questions on group flights, please call Nicolaus and Associates collect at 800+433-2897, or write them at 1201 N. Watson Road, Suite 118, Arlington, Texas 76011.

---

The Research Program on Population and Development Policy, sponsored jointly by the Rockefeller and Ford Foundations, is interested in receiving proposals that examine empirical relationships between development processes and population trends; reciprocal effects of development and population policies; and means by which development processes and population trends might be modified to achieve improvements in human welfare. The submission deadline is July 1, 1976 and awards will be announced in December. For further information outlining application procedures, write The Rockefeller-Ford Foundations' Research Program on Population and Development Policy, The Rockefeller Foundation, 1133 Avenue of the Americas, New York, NY 10036.

---

*Change Magazine*, under a grant from the Fund for the Improvement of Post Secondary Education, has launched a program of undergraduate teaching recognition. The purpose of the program is to identify, with the cooperation of the disciplinary associations, examples of the best efforts to improve undergraduate teaching. Faculty members so identified will receive recognition through publication of a detailed description of their work in a series of reports on teaching. In order to participate, faculty members must share their experiences, through written material and in person, with other teachers, students, and outside evaluators. The experience should be adaptable to other institutions and, if possible, to other disciplines. A complete announcement of this program, together with the criteria to be used in choosing the courses recognized, was published in *Change Magazine*, November 1975. Faculty members interested in submitting an application for consideration should send a brief description of their work to C. Elton Hinshaw, Secretary, American Economic Association, 1313 21st Avenue South, Nashville, Tennessee 37212.

---

*Fulbright-Hays Program for Senior American and Foreign Scholars*

Applications will be accepted this spring for more than 500 university lecturing and advanced research awards during 1977–78 in over 75 countries under the senior Fulbright-Hays program, the Council for International Exchange of Scholars announced recently. Specialists in economics and business administration who are U.S. citizens and have a doctorate or college teaching experience are invited to indicate their interest in an award by completing a simple registration form, available on request from the Council, Eleven Dupont Circle, Washington, D.C. 20036. In April 1976, each registrant will be sent an announcement of opportunities under the 1977–78 program. Applications for 1976–77 are at present under review, but some awards remain open to application. Inquiries about remaining openings are welcomed by the Council.

Each year Fulbright-Hays agencies abroad forward to the Council applications of senior foreign scholars who are interested in remunerative appointments for lecturing and postdoctoral research at American universities or colleges for temporary periods. Approximately 500 foreign scholars are awarded grants to come to the United States after arrangements are made for lecturing or research assignments. Colleges or universities interested in having a foreign Fulbright-Hays scholar on campus during 1976–77 should write to the Council as soon as possible. A directory of foreign Fulbright lecturers and research scholars in the United States is available on request to the Council.

The Fifth World Congress of the International Economic Association, "Economic Growth and Resources," will be held in the Tokyo Prince Hotel, from August 29 to September 3, 1977. The Program Committee is under the Chairmanship of Edmond Malinvaud (France), president of the International Economic Association, with the collaboration of Shigeto Tsuru (Japan), Mekki Abbas (Sudan), Moses Abramovitz (USA), S. Chakravarty (India), T. Khachaturov (USSR), Assar Lindbeck (Sweden), R. Matthews (UK), D. Sadowski (Poland), Robert Solow (USA), O. Sunkel (Chile), H. Uzawa (Japan), C. von Weizsäcker (FRG).

Arrangements are being made to provide special travel and accommodation for participants, including, when desired, pre- or post-Congress tours. Participants will receive periodic information on the progress of its preparation on request to the Local Organizing Committee (Chairman, Shigeto Tsuru), Tokei Kenkyu Kai, 1-10 Shinbashi 4-chome, Minato-ku, Tokyo 105, Japan.

Suggested contributions to the scientific work of the Congress should deal with the general topic of "Economic Growth and Resources," broadly understood, and be submitted to the Members of the Program Committee or sent to the Secretariat of the International Economic Association in Paris, 54 Boulevard Raspail (bureau 428), 75270 Paris Cedex 06, for transmission to the Committee.

---

The Administration on Aging of the Department of Health, Education, and Welfare announces continuation of its Dissertation Research Grant Program for 1976. A limited number of stipends of $5,000 each will be awarded to graduate students at the Ph.D. level in social science who agree to devote one year full time to the research and writing of a dissertation that focuses on the elderly or the aging process. Students in social gerontology, sociology, social work, economics, psychology, political science, public administration, and other relevant social sciences are eligible. The application deadline is March 31, 1976. Copies of the Guidelines can be obtained by writing Dissertation Fellowship Program, Division of Research and Analysis, Department of Health, Education, and Welfare; Office of Research, Demonstrations, and Manpower Resources, Administration on Aging, 400 Sixth Street, S.W., Washington, D.C. 20201.

---

The Conference on Social Sciences in Health is seeking contributed papers for part of its program at the annual meetings of the American Public Health Association in Miami Beach, Florida, on October 17–21, 1976. Interested persons should submit an abstract of up to 200 words as promptly as possible to Irving Leveson, Senior Professional Staff, Hudson Institute, Quaker Ridge Road, Croton-on-Hudson, NY 10520.

---

Omicron Delta Epsilon, the International Honor Society in Economics, invites the submission of entries for the eighth year of the Irving Fisher Graduate Monograph and Frank W. Taussig Award Undergraduate Competitions. The Fisher Award consists of $1,000 and publication as a book by Princeton University Press, subject to approval of its editorial board. In addition, the winner will be invited to submit a paper based on the winning entry to the *American Economic Review*. The recommendations of the Final Selection Board of the Competition will be considered by the *Review* in the refereeing process. All finalists will be invited to submit a paper for publication in *The American Economist*. The Taussig Award consists of $100 and publication in *The American Economist*. Entries for the Fisher Award should be submitted to Departmental Selection Committees by January 1, 1976 and entries for the Taussig Award by May 15, 1976. They will be judged by the International Editorial Board and finalists by the Final Selection Board, consisting of Professors William J. Baumol, Frank H. Hahn, Robert M. Solow, Arnold Zellner, and Egon Neuberger (editor). For more information, write Professor E. Neuberger, Editor, Economic Research Bureau, State University of New York, Stony Brook, NY 11794.

---

The Faculty Exchange Center, founded and administered by faculty members, helps to arrange college and university faculty exchanges within the United States and overseas where the language of instruction is English. For more information, write to Faculty Exchange Center, P.O. Box 1091, Lancaster, Pennsylvania 17604.

---

Papers are solicited for the eighth Amos Tuck School Seminar on Problems of Regulation and Public Utilities, sponsored by the American Telephone and Telegraph Company, to be held August 1–5, 1976 at Dartmouth College. The seminar will be attended by thirty conferees chosen from academic institutions throughout the country. It consists of seven or eight sessions over a four-day period. The sessions provide a forum for the presentation and discussion of new ideas and innovative work in analyzing regulated firms, regulatory processes, and problems of public welfare. Those with an interest in this area are invited to suggest names of possible speakers or to apply themselves. The aim of the seminar is to introduce the research both of young scholars beginning their careers and of scholars who have only recently turned their attention to public utility problems. Therefore, suggestions of speakers must be limited to scholars in these categories. Those chosen to present papers will receive support for research and writing, in addition to travel and living expenses at the seminar. This is not a request for conferee applications. Application forms and further information will be mailed to institutions in March 1976. The directors of the seminar are Professor Duncan M. Holthausen, Jr., and Professor Dennis E. Logue. Please direct all suggestions and correspondence to Directors, Seminar on Problems of Regulation and Public Utilities, The Amos Tuck School of Business Administration, Dartmouth College, Hanover, New Hampshire 03755.

Papers are being accepted for presentation at a conference, "Major International Policy Issues," to be held at the Malibu (California) Campus of Pepperdine University in the fall of 1976. The papers are expected to be policy oriented and to explicate the various dimensions of and alternate policies and consequences related to such major international issues as resource shortages, indexation, detente and disarmament, worldwide stagflation, comparative productivity, comparative quality of life, new economic order, food and population, evolution of economic systems, managed growth vs. limits to growth, trade and aid, multinational corporations, transfer of technologies, international oligopolies, and world monetary systems. Maximum size of papers is 40 typewritten double-spaced pages. Proceedings will be published. Interested scholars should submit preliminary outlines to Professor Nake M. Kamrany, Massachusetts Institute of Technology, Bldg. 20B-221A, Cambridge, MA 02139.

---

The tenth annual meeting of the Pacific Northwest Regional Economic Conference will be held May 6–8, 1976 in Victoria, British Columbia. Academic, business, and government economists concerned with the U.S. and Canadian northwest economies are invited to participate. Persons interested in presenting papers on any subject relevant to the northwest economy are invited to submit abstracts to the program chairman, Professor G. R. Walter, Department of Economics, University of Victoria, Victoria, B.C., Canada, V8W 2Y2.

---

### *Deaths*

Ralph E. Burgess III, international economist, U.S. Treasury Department, Jan. 3, 1975.

Carroll L. Christenson, department of economics, Indiana University, Bloomington, Oct. 11, 1975.

Edward Everett Hale, emeritus professor of economics, University of Texas, Austin, Feb. 3, 1975.

Samuel M. Levin, emeritus professor, Wayne State University, Oct. 2, 1975.

### *Retirements*

J. C. D. Blaine, University of North Carolina, Chapel Hill, June 30, 1975.

Robert W. Bradbury, professor of economics, University of Florida, June 1975.

Elmo L. Jackson, professor of economics, University of Florida, June 1975.

Donald Marschner, professor of business administration, Whittemore School of Business and Economics, University of New Hampshire, July 1, 1975.

Clarence E. Philbrook, University of North Carolina, Chapel Hill, May 31, 1975.

### *Visiting Foreign Scholars*

Emil-Maria Claassen, University of Paris: visiting professor of economics, University of Florida, Jan.–Mar. 1976.

Ehud Kalai, Tel Aviv University: department of managerial sciences, Northwestern University, 1975–76.

Jean Parent, Université de Paris I: visiting scholar, department of economics, Université de Moncton, Sept. 1975.

### *Promotions*

Lewis M. Abernathy: professor of economics, North Texas State University, Sept. 1, 1975.

Byron B. Brown, Jr.: professor of economics, Southern Oregon State College, Sept. 1, 1974.

Steven T. Call: assistant professor, department of economics and Center for Community Leadership Development, University Extension, University of Wisconsin, Milwaukee, July 1, 1975.

Sidney L. Carroll: associate professor, department of economics, University of Tennessee, Knoxville, Sept. 1, 1975.

David A. Denslow: associate professor of economics, University of Florida, Mar. 1975.

Joseph S. De Salvo: professor, department of economics, University of Wisconsin, Milwaukee, July 1975.

Richard J. Gelson: chief, Financial Statistics Division, Federal Reserve Bank of New York, Oct. 16, 1975.

Morley Gunderson: associate professor, University of Toronto, July 1975.

John S. Hill: senior economist, Open Market Operations and Treasury Issues Function, Federal Reserve Bank of New York, Sept. 18, 1975.

Ivan Iskroff: special assistant, foreign department, Federal Reserve Bank of New York, Oct. 2, 1975.

Feng-Yao Lee: professor, department of economics, University of Tennessee, Knoxville.

Fred J. Levin: manager, domestic research department, Federal Reserve Bank of New York, Sept. 18, 1975.

Steven An-Yhi Lin: professor of economics, Southern Illinois University, July 1975.

Milo F. McCabe: associate professor, department of economics, University of South Dakota, Aug. 1975.

Ann-Marie Meulendyke: chief, Securities Analysis Division, Federal Reserve Bank of New York, Oct. 16, 1975.

Garrett A. Vaughn, University of Tennessee: Senate Subcommittee on Antitrust and Monopoly.

Obie G. Whichard, University of Georgia: International Investment Division, U.S. Department of Commerce, Sept. 1975.

## NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, please use the following style:

A. Please use the following categories:

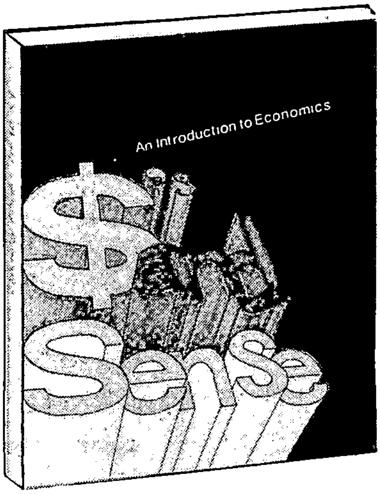
1—Deaths
2—Retirements
3—Foreign Scholars (visiting the USA or Canada)
4—Promotions
5—Administrative Appointments
6—New Appointments
7—Leaves for Special Appointments (NOT Sabbaticals)
8—Resignations
9—Miscellaneous

B. Please give the name of the individual (SMITH, John W.), his present place of employment or enrollment; his new title (if any), his next place of employment (if known or if changed), and the date at which the change will occur.

C. Type each item on a separate 3×5 card, and please do not send public relations releases.

D. The closing dates for each issue are as follows: *March*, November 1; *June*, February 1; *September*, May 1; *December*, August 1.

This announcement supersedes and replaces a letter which was sent annually from the managing editor's office. All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.



# Dollars and Sense
## An Introduction to Economics

Marilu Hurt McCarty
Georgia Institute of Technology

*Dollars and Sense* does *more* with *less.* It covers a balanced selection of macro and micro concepts and applies those principles to many varied real-life situations that are meaningful to students, so that the subject becomes a topic of personal involvement for readers. The result is mastery of the concepts, understanding of how economists apply theory, and practice in independent problem solving.

Concepts and analytical tools are presented simply, followed by examples and applications that relate policies to the individual decision-making level. Each chapter includes learning objectives, self-tests, topics for discussion, and definitions. Special essays on economic issues appear throughout the book. Instructor's Manual with test items.

January 1976, 288 pages, illustrated, paper, $6.95

### National Income Analysis and Forecasting

Edward J. Chambers, University of Alberta
R. Haney Scott, University of Washington
Roger S. Smith, University of Alberta
Complete Instructor's Manual
1975, 406 pages, illustrated, cloth $12.95

### Problems in National Income Analysis and Forecasting
**Revised Edition**

R. Haney Scott, University of Washington
1972, 138 pages, illustrated, paper $4.95

### Macroeconomics
**Analysis and Policy**

# THE AMERICAN ECONOMIC REVIEW

VOL. 66 | MAY, 1976 | NUMBER 2

*PAPERS AND PROCEEDINGS*

OF THE

*Eighty-eighth Annual Meeting*

OF THE

AMERICAN ECONOMIC ASSOCIATION

*Dallas, Texas*

*December 28–30, 1975*

*Program Arranged by* FRANCO MODIGLIANI

*Papers and Proceedings Edited by* RENDIGS FELS AND C. ELTON HINSHAW

PRINTED BY GEORGE BANTA COMPANY, INC.

*Publication Office:* Menasha, Wisconsin 54952

*Executive Office:* American Economic Association
1313 21st Avenue South, Nashville, Tennessee 37212

Correspondence relating to the *Papers and Proceedings,* the *Directory,* advertising, permission to quote, business matters, subscriptions, membership and changes of address should be sent to the Secretary, C. Elton Hinshaw, 1313 21st Avenue South, Nashville, Tennessee 37212. Change of address must reach the Secretary at least six (6) weeks prior to the month of publication. The Association's publications are mailed second class.

THE AMERICAN ECONOMIC REVIEW, including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory,* and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December. Association membership dues for 1976, which include a subscription to both The *American Economic Review* and the *Journal of Economic Literature,* are as follows: $25.00 for regular members with rank of assistant professor or lower, or with annual income of $12,000 or less; $30.00 for regular members with rank of associate professor, or with annual income of $12,000 to $20,000; $35.00 for regular members with rank of full professor, or with annual income above $20,000; $12.50 for junior members (registered students). Certification must be submitted yearly. Subscriptions (libraries, institutions, or firms) are $37.50 a year. Only subscriptions to both publications will be accepted. Single copies of either journal may be purchased from the Secretary's office, Nashville, Tennessee. For foreign postage, add: PUAS countries, $3.20; all other countries and Canada, $3.75.

Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

Price $10.50

# CONTENTS

THE purpose of the American Economic Association, according to its charter, is the encouragement of economic research, the issue of publications on economic subjects, and the encouragement of perfect freedom of economic discussion. The Association as such takes no partisan attitude, nor does it commit its members to any position on practical economic questions. It is the organ of no party, sect, or institution. Persons of all shades of economic opinion are found among its members, and widely different issues are given a hearing in its annual meetings and through its publications. The Association, therefore, assumes no responsibility for the opinions expressed by those who participate in its meetings. Moreover, the papers presented are the personal opinions of the authors and do not commit the organizations or institutions with which they are associated.

# RICHARD T. ELY LECTURE

# Stabilization Policy in Open Economies with Endogenous Politicians

*By* ASSAR LINDBECK*

Stabilization policy has since Keynes been based on two main premises: that macroeconomic fluctuations are largely a result of instability in market behavior; *and* that national aggregate demand management, possibly combined with some restraints in wage bargaining, is the basic means of overcoming these fluctuations.

In this lecture, the emphasis will be somewhat different both in describing the mechanisms of macroeconomic fluctuations and in designing policies to reduce them. Specifically, macroeconomic fluctuations will be seen in the context of a complicated *interaction* between market forces and government behavior, i.e., as an interplay between the economic and the political systems. Moreover, when discussing market forces, the emphasis will be on international rather than national forces.

With respect to policy prescriptions, I will argue that aggregate demand management, though important, is insufficient for a successful stabilization policy. Particularly in distinctly open economies with rather high levels of capacity utilization, there are at least four additional, potentially important types of national stabilization policy: (1) policies designed to influence relative prices; (2) market-improving and mobility-increasing policies; (3) supply management; and (4) selective demand management.

Several of these policies would, if implemented, result in some redesign of the structure of the economic system. Beyond this, however, as government actions often contribute to macroeconomic fluctuations, rather than dampening them, some redesign of the national and international political system too is crucial for an improvement of macroeconomic stability.

The exposition will be organized around three basic, highly interrelated problems of national stabilization policy: (I) the complications related to the international influences on the domestic economy—i.e. "the open economy problem"; (II) the limitations of aggregate demand management; and (III) the tensions between, on the one hand, the political process and, on the other hand, the requirements of a successful stabilization policy.

I shall begin with a technical economic analysis of the first two issues—the open economy problem and the limitations of aggregate demand management. In the last part of the lecture, the problems of the economic system will be explicitly related to the functioning of the political system, and hence stabilization policy be analyzed in the context of the interrelationship between the two systems.

## I. The Open Economy Problem

It is useful to approach the problem about international influences by way of a

* Professor of International Economics and Director of the Institute for International Economic Studies, University of Stockholm. I am indebted to Franco Modigliani and to my colleagues at the Institute for valuable comments to earlier drafts.

model of an extremely open economy and thereafter to investigate how the conditions for stabilization policy will change when the degree of openness is gradually reduced. In particular, I want to show how the relative roles of, on the one hand, *aggregate demand management* and, on the other hand, policies designed to influence *relative prices* depend on the type and degree of openness of the national economy. At the same time, the analysis brings out how the relative efficacy of monetary and fiscal policy depends on the openness of the economy.

### A. An Ultra-Open Economy

Thus, let us start with a mythological "ultra-open" economy model, where (1) all "goods"—commodities, labor and financial assets—are *tradables*, and (2) domestic and foreign goods are *perfect substitutes*. Assuming, to begin with, that exchange rates are fixed and that all goods move freely, domestic prices (excluding indirect taxes and subsidies) of commodities, labor, and financial assets are determined by supply and demand on world markets rather than on national markets. Let us further assume that the country and its firms are so small relative to the outside world that world market prices for all goods are independent of the economic actions of the country itself—the celebrated "small country assumption."

It follows immediately from these assumptions that the room for national stabilization policy is extremely limited in such an economy. Domestic unemployment policy is clearly impossible for the national government, as the labor market is international rather than national. Thus, aggregate demand management is pointless. However, the commodity price level can be influenced by the exchange rate, as well as by tariffs and indirect taxes or subsidies on foreign trade. That is basically all that national stabilization policy can do in this model.[1]

### B. Four Steps Towards the Real World

This caricature of open economies is perhaps a useful approximation for geographical regions within some countries. Let us, however, move somewhat closer to the national economies of the real world. Four steps will be taken in this direction, each one reducing the degree of "openness" of the domestic economy.

*The first step* is to drop the assumption that the labor supplies in various countries are perfect substitutes for each other and perfectly mobile; the labor supply curve that confronts the domestic production sector is then upward sloping rather than horizontal. We may now talk about a *domestic* labor market, though connected with foreign markets. The main implication for economic policy, as compared to the previous model, is that variations in the exchange rate, tariffs, and indirect taxes or subsidies on foreign trade and production may now be used to influence the domestic unemployment level and not just the price level. However, a condition is that the money wage rate does not adjust completely to these policy changes, within the period under consideration, so as to restore the initial real wage rate that confronts firms. Some stickiness of wages in the model is both a reason for unemployment and a prerequisite for influencing output and unemployment by way of exchange rate policy and indirect taxes or subsidies on trade or domestic production. The government can, of course, also reduce unemployment and increase domestic output by

[1] Whereas *unemployment* cannot be influenced, the level of employment and output in the domestic production sector may be affected by way of indirect taxes (or tariffs) and subsidies on foreign trade and domestic production.

employing labor directly and producing output itself.

However, *aggregate demand management* in the commodity and asset markets is still useless. All variations in domestic commodity demand, at a given price level fully "spill over" into the trade account of the balance of payments without any effects on prices or on domestic production and employment. Similarly, all variations in asset demand by the authorities, i.e., open market operations, fully spill over into the capital account of the balance of payments without any effects on interest rates or on domestic private holdings of financial assets and money.

To summarize, in this second model stabilization policy has to rely entirely, except for direct government employment of labor, on policy measures that change *relative prices,* more specifically the real wage rate that confronts firms. In other words, while in this model monetary policy (except exchange rate changes) is useless for domestic policy purposes, there are several types of fiscal policy measures that are potentially useful for influencing the domestic unemployment level (and output): indirect taxes or subsidies on trade and production, as well as direct government demand for labor.

*The second step* toward the real world is to drop the assumption that domestic and foreign tradable commodities are perfect substitutes, which means that total demand (domestic plus foreign) for domestic output can now be represented by a downward sloping aggregate demand curve rather than by a horizontal price line. (The implications are rather similar to dropping the small country assumption for the commodity market.) As a consequence, domestic aggregate demand management, by way of conventional fiscal policy, now becomes a useful tool for influencing domestic output and unemployment—in addition to policy measures that change relative prices. Moreover, if not only wages but also prices are sticky downward, as they are in the real world, ordinary Keynesian-type "demand failures" with unemployment disequilibrium may take place, which increases the scope for aggregate demand management even further.

If, as *a third step,* nontradable commodities are introduced in the model, the national autonomy of demand management by way of fiscal policy is further increased—for domestic unemployment as well as the general price level—since there is no foreign component at all in the demand function in this market.

Monetary policy is, of course, still useless as a tool of demand management for domestic purposes, so long as we stick to the assumption that all financial assets are tradables and that foreign and domestic assets are perfect substitutes (at fixed exchange rates). If this doubtful assumption (which seems to have been taken as a realistic description of the real model by many theoretical model-builders) is removed, as *a fourth step* towards the real world, monetary policy too will be useful as a tool of demand management. More generally, open market operations will be more effective in influencing the domestic economy the less the substitutability between domestic and foreign financial assets is, as compared to the substitutability between domestic financial assets and money. The reason is that the lower the former substitutability, the smaller the fraction of open market operations that will "leak" abroad, thereby offsetting the effects on domestic money and credit markets of open market operations. In the real world, both specific institutional conditions in the credit market and the use of nonconventional monetary and fiscal policy instruments, mainly tools that create wedges

between the rate of return of foreign and domestic assets, can significantly increase the national autonomy of stabilization policy even in otherwise rather open economies.

*C. The Relative Openness of Markets*

What has been said so far illustrates the fact that the less open the economy and the less flexible domestic wages and prices, the more useful aggregate demand managment will be as a complement to policy measures that change relative prices (such as exchange rates and indirect taxes or subsidies). The discussion has also underlined that the *relative* openness of different markets—for labor, commodities and credit—is crucial for the efficacy of various policy tools. The relative openness of the labor and commodity markets has some additional implications with respect to the performance of stabilization policy. For instance, the rather realistic assumption that the commodity market is more open than the labor market yields some important conclusions.

First, international inflation would then be expected to be transmitted among nations *largely* by way of a "direct price influence" on tradables and possibly also an indirect price influence on nontradables via wage formation. The more important this direct and indirect "price link" is, the less important the multiplier effects and the monetary effects via the balance of payments should be. This conclusion rests, of course, on the assumption that prices for domestic tradables are primarily determined in the world market rather than by domestic economic activity and hence domestic demand and supply conditions. The inference, in fact, is consistent with the observed tendency in recent years for inflation also to be transmitted internationally to countries with considerable domestic slack (due, for instance, to restrictive domestic demand management). It is also consistent with the experience in macroeconometric model building that it has been difficult in many countries to identify the excess demand situation in the domestic commodity market as an important factor behind the rate of domestic price change. Thus, the apparent limited sensitivity of domestic prices to *domestic* demand conditions may not be a result only of rigidly "administered prices"; the geographical market domain may partly be misspecified in the models.

Secondly, the real wage rate and therefore also the rate of return on physical assets in the tradable sector, as well as the relative price between tradables and nontradables, can easily become "out of line" in economies where the commodity market is highly open relative to the labor market. The reason is that whereas the price level for tradables is determined primarily in the world market, nominal wage rates are directly determined by domestic circumstances, such as by excess demand in the national labor market, by domestic price expectations, and by specific national circumstances for wage bargaining, which are often in fact related to the national political situation.

Thus, an "improper" real wage rate, with a concurrent low profitability level, can be expected to be a more frequent reason for unemployment, low investment incentives, and a current account deficit in economies where the commodity market is open relative to the labor market than in economies where the degree of openness is about the same in both markets. This means that policies designed to influence the real wage rate will be more important for investment, employment, and the current account, the more open the commodity market is relative to the labor market. As an empirical generalization, I think it is safe to say that stabilization policy has suffered considerably in many countries from a neglect of relative prices

—such as the real wage rate, the relative price between tradables and nontradables, and in particular profitability—as compared to aggregate demand. The United Kingdom is an obvious example.

This means that whereas for a closed economy *any* point on the long-run Phillips curve may be regarded as an equilibrium point, there is in principle only *one* equilibrium point on the long-run Phillips curve for an open economy in the sense that only one point is consistent with both constant inflation and an unchanged position for the current account of the balance of payments (normally at the point where domestic and foreign cost increases are equal). With floating exchange rates, any point on the long-run Phillips curve can in principle be chosen, just as in a closed economy.

A third inference from this analysis is that it does not make much sense for small countries to fight inflation by cutting back domestic aggregate demand (rather than revaluing) if inflation is brought about by international price changes. In this specific sense, the government in a small country can often tie aggregate demand management to unemployment and current accounts targets, rather than to the price target. This was, in fact, what most small countries did in the 1974-75 stagflation period, when they let the large countries alone fight world inflation by way of demand-reducing polices and drastically lower capacity utilization. Most small countries could, and did, take "free rides" on the anti-inflationary policies of the big countries—as long as the governments in the small countries were willing to accept a deterioration in the current account of the balance of payments. Perhaps it should be added that having taken advantage of the free ride, the small countries could then boast how much more successful they were than the large countries in sustaining high employment!

Let us also combine the earlier assumption about a basic difference in price formation behavior between commodities and labor, and between tradables and nontradables, with an assumption about a difference in the rate of productivity increase between these two commodity sectors. Let us also add an *accommodating economic policy on the demand side*. It is then possible to derive rather strong theorems about antiinflationary policies in an individual country.

*First of all*, recommendations in incomes policy discussions have usually been based on the assumption that price stability can be achieved by restricting the rate of nominal wage increase for the economy as a whole to the average rate of productivity increase for the economy. This recommendation has to be strongly modified in an open two-sector model of the type discussed here if the rate of productivity increase is smaller in the nontradable than in the tradable sector, and if wages tend to develop in a parallel fashion in the two sectors. For prices of nontradables would then rise in spite of a proportional development of wage rates and productivity for the economy as a whole, and there is no reason why prices would *fall* in the tradable sector, to "compensate" for the price rise for nontradables, in a fixed exchange rate regime. The conclusion is, of course, that continuous revaluations are necessary for stability of the general price level, even if world market prices for tradables are constant and the rate of wage increase in both sectors is equal to the increase in productivity for the economy as a whole.

*Secondly*, another widely heard recommendation for fighting inflation has been to step up the rate of productivity growth, particularly in manufacturing, for instance by way of harder work, higher investment, and more rapid improvements in technology. However, a faster rate of productivity increase for tradables would, in an

open two-sector model of the type discussed here, tend to *increase* the rate of inflation as long as the exchange rate is fixed. The reason is that the "room" for wage increase (at constant profit margins) in the tradable sector would then go up, generating a more rapid wage increase. When these wage increases are spread to the nontradable sector, the rate of price increase there will go up without any "corresponding" fall in the rate of price increase in the tradable sector, where prices are tied to the world market. By contrast, a faster rate of productivity increase for nontradables, such as for many services, would clearly help reduce inflation.

In fact, in the extreme case where (1) prices for tradables are "parametrically" determined by the outside world, (2) profit margins are constant, both in the tradable and the nontradable sector, and (3) a "cost-accommodating" policy is pursued on the demand side, the average price level would increase by the *sum* of the rate of the exogenous price increase for tradables and the difference in the rate of productivity increase between the two sectors, the latter variables being weighted by the share of nontradables in the overall price index.[2] A model of this kind corresponds to what in the international literature has been called "The Scandinavian model of inflation" (Aukrust; Edgren-Faxén-Odhner). Of course, countries tending to inflate more rapidly than this can do so by devaluing from time to time, and countries tending to inflate less can do so by concurrent revaluations.

### D. Flexible Exchange Rates

The last points illustrate the usefulness in macroanalysis of a disaggregation between tradables and nontradables and of looking at the relative price between these. The analysis also illustrates the well-known fact that exchange rate flexibility, either through discretionary changes or freely floating rates, is a *necessary* condition for a reasonably independent national price trend. It is also clear that exchange rate flexibility can partly shield the economy from volume fluctuations on world markets by appreciations in world booms and depreciations in world recessions—occasionally an example of a "beggar-thy-neighbor policy."

However, the degree to which this shielding from international price and volume fluctuations takes place depends both on the type of international disturbance and on the monetary and fiscal policy pursued in the country in question. For instance, the economy may be shielded rather well from proportional increases in world prices for *all* tradables by way of an appreciation of the exchange rate in proportion to the international price increase. On the other hand, it is well known that different rates of price change for different products (including terms-of-trade changes) are less effectively handled by exchange rate changes, since stability of the general price level then requires

[2] Make the following notations:

$p_w$ = rate of price change for domestic tradables on world market;

$p_T$ and $p_N$ = ditto for tradables and nontradables, respectively, on domestic market;

$e$ = rate of change of exchange rate;

$w_T$ and $w_N$ = rate of wage change in tradable and nontradable sector, respectively;

$q_T$ and $q_N$ = rate of productivity increase in tradable and nontradable sector, respectively;

$\alpha$ = weight in price index for tradables.

The basic *assumptions* of the model then are:

$$p_T = p_w + e; \qquad w_T = p_w + e + q_T = w_N;$$
$$p_N = w_N - q_N = p_w + e + q_T - q_N.$$

The *inference* for the rate of change of the price level is:

$$\begin{aligned} p &= \alpha \cdot p_T + (1-\alpha)p_N \\ &= \alpha(p_w + e) + (1-\alpha)(p_w + e + q_T - q_N) \\ &= (p_w + e) + (1-\alpha)(q_T - q_N). \end{aligned}$$

Thus, the domestic price index will rise by the *full* value of $p_w$ and $e$, and by the weighted difference between $q_T$ and $q_N$.

reductions in prices for some commodities to compensate for price increases for others, and this may be difficult to achieve in a world with limited price flexibility downwards.

In addition, in a *floating* rate system, isolated import price increases may easily lead to market-induced depreciations, which tend to accentuate the inflationary price influence from abroad—as in Japan and the United Kingdom after the oil price increase. Moreover, both theoretical considerations and empirical evidence suggest that it is *portfolio shifts* that, in the short run, dominate exchange rate developments in a floating exchange rate regime (and reserve movements in fixed rate systems). (See, for instance, P. J. K. Kouri.) Thus in a regime of floating rates, shifts in portfolios by foreign and domestic asset holders may create considerable disturbances of the domestic price level, as well as of profitability and the allocation of resources, via induced changes in exchange rates, particularly if price increases are (partly or wholly) irreversible.

Basically, much of this simply illustrates the Jan Timbergen rule of economic policy, according to which two targets cannot as a rule be achieved with one policy instrument. In general, we should not expect a given exchange rate change to bring about the desired development of *both* the balance of payments *and* the price trend, if other policy instruments are not adjusted accordingly. More specifically, if money wages react strongly and rapidly to exchange rate changes brought about either by official interventions or by portfolio shifts, it is the domestic price level, rather than the balance of payments, that is affected by the change in the exchange rate. If, by contrast, money wages do *not* respond much to exchange rate changes, these will influence the balance of payments rather than the price level. In general, the more efficient exchange rate changes are in influencing the balance of payments, the less efficient they are in influencing the price trend, and vice versa. Thus, what will actually happen in a specific situation to the price level and the balance of payments after a change in the exchange rate depends both on the system of wage formation and on the demand management policy that is actually pursued, including the monetary policy.

## II. Limitation of Aggregate Demand Management

A main conclusion of the previous analysis was that a successful stabilization policy *in open economies* cannot rely only on aggregate demand management; relative prices between tradables, nontradables, and labor are also highly relevant. The case for a heavy reliance on policy measures that change relative prices can be put even stronger if three additional limitations of aggregate demand management are emphasized: (1) the importance of substitutions between periods for stabilization policy; (2) problems connected with the heterogeneity of the commodity and labor markets; and (3) difficulties related to competing claims of various organized groups in society. Let us look at these three aspects in turn—still neglecting the complications for stabilization policy that are embedded in the political system.

### *A. Substitutions between Periods*

Since a main purpose of stabilization policy is to change the *timing* of spending, policy tools that create substitution effects between periods via changes in relative prices between periods are particularly useful. It is from this point of view that interest rate changes have always been regarded as appropriate for stabilization policy, the interest rate being a relative price between variables in different periods. However, similar ef-

fects can be obtained by *temporary* changes in indirect taxes or subsidies on spending and/or production—of consumption as well as investment. Some European countries have, in fact, experimented with such measures—with some success.[3] Indirect taxes and subsidies of this type also have the advantage of "striking directly" on what we want to affect—the *flow* of spending on investment or consumption—rather than, like interest rate changes, on the market value of the *stock* of earlier issued financial assets. Furthermore, indirect taxes and subsidies can be used also when the external constraint limits the use of interest rate policy.

While changes in *direct* taxes on households that are expected to be temporary may have very small effects on spending, due to the fact that consumption in one period is a function of the path of past and expected future income, *temporary* indirect taxes can overcome this deficiency by creating substitution effects between periods (Lindbeck 1963, Chaps. IV and V). To achieve similarly strong short-term effects by way of temporary changes in direct taxes or transfers, very large doses may be necessary.

If stabilization policy in major countries during the 1974-75 recession had relied more on temporary reductions of indirect taxes or temporary increases in subsidies on consumption as well as investment, stabilization policy would probably have been much more successful in stimulating the economies without accelerating inflation—assuming that this really was what the governments wanted. In fact, reductions in indirect commodity taxes or increases in indirect subsidies seem ideally suited in situations of "stagflation," as such measures both limit inflation (of market prices) and reduce unemployment.

[3] Norway, Sweden and West Germany are examples. For an account of the Swedish experience, see Lindbeck 1974.

### *B. Heterogeneity of Commodity and Labor Markets*

Another obvious weakness of "pure" *aggregate* demand management is that excess demand in the commodity and labor markets is often very unevenly distributed between various submarkets. A policy that tries to realize full employment by way of aggregate demand management only is therefore likely to run into bottlenecks and higher inflation long before "full" capacity utilization is reached for the weakest sectors of the economy.

If we are not satisfied either with a rather low average level of capacity utilization or with the rate of inflation, in fact possibly an accelerating one, that follows from an economy with excess demand in many submarkets, there seem to be at least three alternative strategies—still neglecting the mutual interaction between the economic and the *political* systems.

*One strategy* is increased factor mobility of labor as well as capital. In the case of labor, this would mean greater flexibility of relative wages and cheaper and better organized systems for labor exchange and retraining and other labor-mobility-increasing features. I will not dwell on this well-known and rather generally accepted point.

*A second strategy* would be "supply management" as a complement to demand management. The basic idea would be to stimulate capacity increases in sectors that are likely to be bottlenecks in the next boom. This point is relevant at least for some nontradables, perhaps mainly for the public infrastructure and sectors where the government controls prices and/or output. In many cases, simply a removal of government regulations, which often distort relative prices and create bottlenecks, may be the most efficient type of

supply management. A slightly more interventionist version of supply management would be to try to "flatten out" the short-run supply curves for goods and services by subsidies for the employment of high-cost labor (such as employees with poor training or with various handicaps)—and perhaps also to give temporary subsidies to the new hiring of labor in general, in particular during a recession. The idea is, of course, to limit the size of the increase in market prices—via a devaluation or increased domestic aggregate demand—that is necessary to induce increased output and employment. (See Rehn.)

*A third strategy* would be "selective demand management" in order to adjust the composition of demand to the composition of productive capacity between sectors and regions. The idea is, again, to avoid bottlenecks, largely by a conscious manipulation of relative prices, when higher capacity utilization is approached.

In general, we could perhaps say that in the same way as rigidities of the average wage and price *levels* create a need for aggregate demand management, rigidities in *relative* wages and prices make a case for mobility-promoting policies, and selective supply and demand management. As criteria for the "composition" of such short-run selective demand and supply management could perhaps be used the distribution between sectors and regions of vacancies, unused capacity, inventories, unfilled orders, delivery times, etc.

A more specific argument for such policies is that macroeconomic disturbances may occur at different points in the macroeconomic system and that it may be better to counteract these disturbances where they take place, rather than to try by way of broadly based demand policies to prevent them from influencing macroeconomic target variables (Lindbeck, 1963, pp. 151-73).

Policies of these types have to be classified under the nowadays rather dirty word "fine tuning." However, it is important to stress that there are at least two different kinds of "fine tuning."

*One* type is that the government tries continuously to keep aggregate demand very close to the capacity ceiling of the economy, which tends to create a situation with excess demand ("bottlenecks") in many sectors simultaneously with excess supply ("slack") in others. It was this type of fine tuning that ran into severe problems during the late 1930's and early 1970's.

A *different* type of fine tuning, which has been discussed here, is to be very "modest" with expansions of aggregate demand after a rather high, but not quite "full" level of capacity utilization has already been reached, and instead try to achieve full employment by way of factor mobility policies and selective demand and supply management. This type of "selective fine tuning" is, in fact, quite consistent with the theory of "the natural rate of unemployment," as the policy implication of that theory is that attempts to remove unemployment, below a certain level, by way of increased aggregate demand, is self-defeating. It is, of course, an open question, in practice, whether full employment policies by way of selective fine tuning could have avoided the acceleration of inflation in the world that followed the continuously higher average level of capacity utilization in the Western world from the mid-1950's to the late 1960's and early 1970's.

### C. Competing Claims

Another macroeconomic aspect of relative prices is that *organized groups* in our present day economies—labor unions, farmers' organizations, employers' organizations, large corporations, and public authorities—try to use their market power to change relative prices in their

favor in the struggle for income shares and relative factor returns. It is well known that aggregate demand management may not eliminate inflation due to such competing claims, unless the policy is extremely restrictive and unemployment-creating.

In cases like these, inflation should not be regarded as an "effect" of a change in some *specific* variables—such as "exogenous" spending, open market operations, or the quantity of money—but rather as a common *process of adjustment* of the economy to various types of inconsistent claims, with some groups being disappointed at every point of time. The process presupposes, of course, a "cost-accommodating" demand management policy including an accommodating supply of money and credit.

A specific and increasingly important aspect of the struggle for income shares is the inconsistency of claims by the public and private sector. For instance, it has been noted in many countries that labor unions often ask for "compensation"—in the form of wage increases—to offset tax increases designed to finance increased public spending. This means that attempts by the authorities to fight demand inflation are likely to result in cost-push inflation instead. What makes this conflict ironic is that the labor unions which try to compensate themselves for tax increases are often the very same pressure groups that lobby for the increased government spending that has made the tax increases necessary.

If this type of compensation mechanism operates also for *automatic* tax increases, i.e., when tax revenues increase at given tax rates due to higher national income, the theory of automatic stabilizers on the demand side has to be reformulated to allow for the destabilizing effects on the cost side. When wage demands are based on such ambitions to protect after-tax real income, quite explosive wage-price spirals may be created in countries with highly progressive tax systems—if aggregate demand management is "permissive" in order to prevent unemployment. The basic reason for these problems seems to be the same as why deteriorations in the terms of trade may create domestic wage-price spirals of "cost-push type": real income resistance of income earners. Thus, conflicts about *relative* incomes and wages are not the only reason for spirals of this type; concern and disappointment about *real* disposable incomes may also generate such spirals.

If the progressiveness of the tax system is very high, it is easy to show that the only chance for employees to obtain increases in their real disposable wages may be to accept *reductions* in nominal wages and hence "cheat" the government on real disposable income by "exploiting" the progressiveness of the tax system "in the reverse direction," and as a consequence lowering the public share of national income (Calmfors-Lundberg, pp. 122-29; Lindbeck 1974). However, this is certainly very difficult to bring about in practice, as it presupposes both collusion between most groups of income-earners, and downward price flexibility.

The main conclusion of these considerations is probably that *both* widespread dissatisfaction concerning the distribution of income *and* a rapid expansion of the public sector, in particular in the context of an extremely progressive tax system, in reality are difficult to reconcile with reasonably stable prices. This is hardly a comfortable conclusion.

## III. The Political System: Endogenous Politicians

The previous analysis has been somewhat "non-Keynesian" in its emphasis on relative prices and profitability and not just (or mainly) on aggregate demand. However, the analysis has been in line with conventional Keynesian philosophy

in the sense that it has been based on the view that we live in an unstable market system, which could and should be stabilized by conscious economic policies of national governments. Such recommendations, however, neglect instabilities and imperfections in the political-administrative system. This is clearly a nonsymmetrical treatment of conceivable deficiencies in the market system and in the political-administrative system.

This does not mean that we have to swing to the other extreme, and assume, like the Chicago school, that the world is just the other way around: that we live in a highly stable market system which from time to time is upset by destabilizing actions taken by governments. Instead, I think that the most reasonable approach, at the present state of knowledge, is to assume that there are instabilities and imperfections in *both* the market system *and* the political-administrative system, and that these interact in a complex way. It is obvious that macroeconomic fluctuations today are so intimately connected with government policies that realistic explanations and forecasts of macroeconomic fluctuations require that government behavior be analyzed as an integral part of the fluctuations. For instance, it seems that the differences between various short-term economic forecasts today depend less on divergent views on the functioning of the private sector than on different assumptions about the future economic policy. An important aspect of such assumptions is various hypotheses as to how governments most likely will react to future economic events. This means that it is useful to treat the government as an *endogenous* rather than an exogenous variable in the macroeconomic system.

### *A. Political Behavior Functions*

Granting the need to "endogenize" politicians, it is obvious that this can be achieved in several alternative ways. One approach to the positive theory of political behavior is to assume that politicians are well informed and idealistic "guardians of the general good" (as defined, perhaps, by the ideology of the government). This would mean that the *normative* behavior functions derived from the welfare theory of economic policy—as developed by Tinbergen, James E. Meade and others—would be interpreted also as *positive* behavior functions of politicians.

An alternative approach to the theory of political behavior is to take the opposite position and assume, like Anthony Downs, that politicians are concerned with their own welfare, obtained by seizing and staying in power, rather than with the welfare of society as a whole. More specifically, a politician in a democracy is then, to quote Downs, regarded as "an entrepreneur selling policies for votes instead of products for money" (Downs, p. 137). Analytically, behavior functions for politicians could then be derived by replacing an "idealistic" preference function of politicians à la Tinbergen-Meade with a vote-getting function, which is maximized subject to the constraints defined by the trade-off possibilities between the various vote-creating variables.

A more "eclectic," and I think more realistic, approach would be to combine the idealistic and the popularity approaches, with the relative weights between the idealistic variables and the popularity variable changing systematically over time during the course of an election period—the popularity variable gaining weight relative to the idealistic variables when an election day is approached, which would mean that the Downs theory would be approached when the election comes closer. In an explicitly intertemporal model we could, with some exaggeration, say that as the time to the election approaches zero, the discount rate for the future economic variables goes to infinity. Every government wants, of course, to be-

lieve that this type of behavior coincides with what is "the general good for society as a whole" *in the long run*.

On the basis of this eclectic approach to the theory of economic policy behavior, three sets of relations have to be specified: (1) the properties of the asserted target-preference function of the government, i.e., a specification of both the idealistic and the popularity variables in the function, and their relative weights at different points of time; (2) a specification of how the popularity variable is influenced; and finally (3) a specification of the economic constraints within which the maximization of the target-preference function is supposed to take place, in particular a description of how the government can influence the economy. (For approaches along these lines, see for instance Frey-Lau; Lindbeck 1973).

*B. Endogenous Stabilization Policy*

When *stabilization policy* is discussed, it is probably important to include in the target-preference function at least four "idealistic" variables, each one characterized by falling marginal utility, or rising marginal disutility: real disposable income of households, unemployment, inflation, and the current account of the balance of payments (or the stock of reserves)—and most likely also the rate of change of these variables. When choosing an appropriate popularity variable in the preference function, several alternatives are possible. An expression for party sympathies among the electorate is perhaps a reasonable variable, operationally defined for instance as "sympathy" answers to Gallup polls.

It is likely that the popularity variable is influenced by approximately the same variables as we have chosen to treat as idealistic variables in the target-preference function, though possibly with different weights and different timing. In particular, I will make two assumptions which make a preference function that includes both idealistic variables and a popularity variable differ substantially from one which includes only the idealistic variables: (1) *Recent* events are assumed to be considerably more important for the popularity of the government than events long ago—an assumption about a "short memory" of voters. (2) The electorate is assumed to have very imperfect knowledge about the *future* effects of policy actions, such as effects that emerge after the next election.

That voters are interested in their real income and possibly its rate of change is, of course, consistent with conventional micro theory of household behavior. Moreover, a number of empirical studies indicate that governments tend to gain popularity in periods of prosperity and rising real income and lose it in periods of depression and falling (or only slowly rising) real income (Kramer; Åkerman).[4] Considering the important role, in the political discussion after the Second World War, of inflation, unemployment, and the current account of the balance of payments (or possibly the level of exchange reserves), and their rates of change, we should also expect these variables to be important for the popularity of a government. In fact, several empirical studies suggest that this is the case (Lepper; Nordhaus).

On the basis of these assumptions, we would expect two characteristic features of government behavior over the cycle.

*First*, due to the assumption of increasing marginal disutility of inflation, unemployment, and current account deficits, we would expect shifting emphasis on the various macroeconomic policy targets as

[4] There is an identification problem here, however, in countries where the government can choose election time: elections may be held in periods of rising real disposable income, rather than the other way around. Or both may have been deliberately influenced by the government.

these variables happen to change themselves due to exogenous disturbances—even without consideration of the popularity variable and also without having to assume any shift in the target-preference function. Inflation, current account (or balance-of-payments) deficits, and unemployment will succeed each other as "the Enemy Number One of the Country," thus generating a stop-go policy cycle in response to factual events.

*Secondly,* as soon as we also take account of the popularity variable in the target-preference function, we would expect that the closer we are to an election, the more inclined the government is to take expansionary actions. This conclusion follows already from the introduction of real disposable income, and/or its rate of change, in the popularity function, because of the ease and speed by which governments can "buy" popularity, and hence votes, simply by raising temporarily real disposable incomes of households *directly*—by way of tax cuts and increases in transfers and public consumption. The inference that expansionary tax and expenditure measures undertaken to boost disposable incomes of households tend to be large and frequent immediately before elections is, in fact, quite well confirmed by empirical data. For instance, Edward Tufte found in a multi-country study that disposable income usually has tended to go up immediately before elections—in fact in 21 out of 26 democracies studied (Tufte). In many cases, these increases were brought about by fiscal policy measures with a direct impact on real disposable income.

The other macroeconomic variables—inflation, unemployment and the current account—are much more difficult to manipulate by the government. However, let us assume that the government thinks, quite realistically, that it can expand output, at least for a while, by increasing excess demand for commodities and labor, and that the rate of inflation goes up *significantly* only after a time lag. In other words, it is assumed that an expansion of aggregate demand, to begin with, generates a movement up along a given short-term Phillips curve and that an upward shift of the curve will only occur later, if at all. These considerations further strengthen the conclusion that expansionary policy actions should be expected immediately before elections in order to reach a point as close as possible to the origin in a three-dimensional diagram with inflation, unemployment and the current account deficit on the three axes.

The model also predicts that the government will usually cut back aggregate demand after the election in order to bring down the rate of inflation, to squeeze out inflationary expectations and hence to shift down the short-term Phillips curve, as well as to reduce the deficits in the current account, well in time before the next election, so that new expansionary actions can be undertaken again before that election without immediately running into high inflation and a large current account deficit. The experiences of recent years have shown how high the economic and social costs are during this deflationary phase of the policy cycle.

This type of behavior would *contribute to,* though not necessarily generate, "clockwise loops" in a conventional price-Phillips-curve diagram, with the timing, in calendar time, of the loops influenced by the attempts of the authorities to reach positions on these loops as close as possible to the origin during the months immediately before election. Tendencies to such loops can, in fact, be noticed in several countries during the last decade (Grossman; Lindbeck 1975; Nordhaus).

Thus, when the responsibility for macroeconomic stability is relegated to the politicians, it is unavoidable that the interpre-

tation and the implementation of this responsibility become strongly colored by the specific features of the political system, in particular by short-term vote-getting considerations, and that the business cycle therefore becomes a mixture of economic and political forces interacting with each other.

Of course, it is possible to reach more specific conclusions about the timing of these loops if the model is specified in more detail. For instance, it is not only conceivable but likely that the general public is more concerned with the *rate of change* than with the *level* of unemployment, at least as long as the level is not higher than has usually been the case during the postwar period. The reason is that a moderate level of unemployment only hits a small fraction of the population, whereas *increasing* unemployment creates lower job security for a considerable fraction of the population. There is, in fact, some empirical evidence for this in the sense that election outcomes seem to be more sensitive to the *change* than to the *level* of unemployment (Lepper).

If this is a correct hypothesis, and if it is also understood by the politicians, we would expect that the government is satisfied just to have passed "the lower turning point" of the inflation-unemployment loop shortly before an election, in order to reach, before the election, a situation with *falling* unemployment and still relatively modest inflation. On the basis of this theory, it is natural that the governments in the U.S. and West Germany waited so long to take expansionary actions in the 1974-75 stagflation period in view of the fact that the next election in both countries will not occur until the fall of 1976.

Many open economies also show a macroeconomic development pattern where a rapid increase in unit labor costs results for a while in squeezed profits and lagging investment and employment in the tradable sector, as well as a reallocation of resources to the nontradable sector, largely in fact to the public sector. After a while, a devaluation, or possibly a slowing down of wage inflation by way of a more restrictive economic policy, restores profits and investment incentives in the tradable sector, possibly followed by a new phase of falling profits, etc. Thereby a second type of political-economic cycle is superposed upon the short-term business cycle: a profit-investment-devaluation-demand management cycle, usually with a longer periodicity than the ordinary business cycle. We find such a cycle in several countries, such as the United Kingdom, Denmark, Finland, as well as in many LDCs.

### *C. Implications of Endogenous Policy*

*In reality* we would expect that the control by the authorities of the business cycle is very imperfect, judged from the point of view of both the idealistic and the popularity variables. The earlier mentioned loops in inflation-unemployment space would therefore be expected to be rather irregular. There are several reasons for this: (1) the high frequency of exogenous shocks that continuously hit the economy, for instance from international sources; (2) the limited understanding among politicians and their advisers of the functioning of the very complex macroeconomic system; (3) the "imperfections" in the political-administrative system, including the celebrated "policy lags"—recognition lags, decision lags, and effect lags; and (4) the delicate balancing of the interests and opinions of various organizations which challenge the authority of the national government and often succeed in modifying both the actions of governments and the effects of such action.

All this put obvious limits on the possibilities of a successful fine tuning of the mixed economic and political business

cycle.

In the context of this model—with a complicated interaction between markets and policies—it is not downward flexibility of the price and wage *level* that is important for the employment level, but rather the flexibility downwards in the *rate of change* in wages and prices. Moreover, it is not mainly the *automatic* effects of price and wage changes on private behavior, such as on demand for commodities and labor—via real wages, interest rates and real balances—that is important, but the effects of such flexibility on *government behavior*.

More specifically, the more sensitive downwards the rate of price change is to reductions in aggregate demand, the shorter are the periods of unemployment that are necessary. In other words, the lengths of the "stop" periods in the go-stop cycles would be expected to be inversely related to the degree of downward flexibility of the rate of inflation. Hence, it is crucial for economic stability that institutional changes are brought about which make the rate of wage and price increases *more sensitive downward* to reductions in capacity utilization—as well as, of course, *less sensitive upward* to increased capacity utilization. Thus, the lag between quantity and price changes is both a prerequisite for the contemporary "political business cycle" and a reason for the duration of the stagflation periods.

Unfortunately, it is not very clear how such policies and institutional reforms could be brought about. In the case of commodity markets, increased competition, including international competition, and public studies on price setting behavior are often mentioned as potentially useful reforms (though such reforms may increase price flexibility *upward* as well, at very high levels of capacity utilization). Personally I would not object to the breaking up of some large corporations into somewhat smaller units. In the case of the labor market, increased competition, by way of a drastically reduced role of labor unions for wage formation, is hardly a feasible strategy in most countries—in view of the political role of labor unions. However, an increased understanding in society that aggressive wage policies and rigidity of relative wages in fact create and prolong unemployment periods could certainly help. It is perhaps too much to hope that governments would be able to limit inflationary wage increases by *announcing* before wage bargaining that aggregate demand in money terms will only be allowed to increase by a certain limited amount—though the West German government seems to have done just about that on some occasions, with considerable success.

It is very unfortunate that we economists are so empty-handed on this strategic issue in stabilization policy concerning institutional reforms that make the rate of price increase less sensitive upward and more sensitive downward to variations in capacity utilization.

### *D. Endogenous Targets and Instruments*

A changing relative emphasis over time of the various target variables has been analyzed here as movements along a given preference function, with a given set of policy instruments, rather than as shifts in this function. A more general approach would also include as endogenous elements in the analysis (1) shifts in the evaluation of the target variables and (2) the development of new policy tools.[5]

One hypothesis along the first line would be that "policy successes" for a certain

[5] Changes in the tradeoff possibilities can, of course, also have fundamental consequences for such "shifts of emphasis." For instance, governments have often reacted to increased frictional or structural unemployment (with large elements of "voluntary unemployment") by further increasing aggregate demand—also when the frictional or structural changes are in fact caused by the government itself, for instance via more liberal rules for unemployment benefits.

target variable create a tendency among politicians to raise the level of aspiration for this specific policy target. An obvious example is the increasingly ambitious formulations of the "full employment" target in many countries during the 1950's and 1960's when employment policy was very successful. Politicians started to argue that a low general level of employment was not enough, and also that "remaining pockets" of unemployment for specific regions, branches, and types of labor should be removed, thus making the unemployment target more and more differentiated.

Moreover, from the mid-1960's the tolerance for inflation increased in most countries along with the failures to achieve price stability; a rate of inflation characteristic of the peaks of previous booms became more and more regarded as minimum achievable "low points." Similarly, the failures in full employment policy during the international recession of 1974-75 seemed to have lowered dramatically the ambitions of full employment policies; levels that only recently were regarded as "politically impossible" were after a while regarded as levels to strive for, when the observed rates were much higher.

Thus, adjustments of the political aspiration level seem to work in both directions —raising aspirations as a response to success, and reducing aspirations as a response to failures—rather similar to the "psychological" analysis of household behavior by "the Katona school," and the analysis of "satisfying behavior" of firms by "the Carnegie school."

Moreover, both the successes and the failures of stabilization policy seem to stimulate a search for new policy tools. For instance, the early successes of broad full employment policies, and therewith connected increasingly ambitious full employment targets, made politicians develop new policy tools designed to deal with the new more ambitious targets, such as selective subsidies and retraining programs to remove pockets of unemployment in specific regions and branches of industry, and for specific groups of employees such as married women, minority groups, the handicapped, etc. Similarly, the striking policy failures in many countries with respect to price stability and balance-of-payments equilibrium in the early 1970's generated a search for a whole new set of policy tools or the restoration of tools which had not been used for a long time—such as price and wage controls, new types of selective taxes and subsidies, and various tools designed to create barriers between domestic and foreign asset markets.

The general conclusion would be that whereas success and failure with a policy target seem to change the level of aspiration up *or* down in response to successes and failures, respectively, both successes and failures seem to generate a search for new policy tools. The result is a gradual proliferation of new policy tools.[6]

These observations provide additional examples of the importance of endogenizing the behavior of politicians.

## IV. Concluding Remarks

Three basic weaknesses of national stabilization policy have been scrutinized in this lecture. The first one was connected with the international economic influences on the domestic economy, and the second, which is common for open and closed economies, with the inadequacy of aggregate demand management. The suggested remedy for both these weaknesses was to amend aggregate demand management with more differentiated policy tools, mainly designed to influence relative

[6] These generalizations probably have exceptions. After a period of particularly large policy failures, it is conceivable that the policy ambitions are lowered so much that fewer policy tools than earlier are necessary.

prices of commodities and factors as well as profitability, but also to increase factor mobility and to affect the *composition* of aggregate demand and aggregate supply.

However, policies along these lines would further accentuate the third discussed weakness of stabilization policy: that the functioning of the political system is not always in good harmony with the requirements of stabilization policy. The implementation of differentiated and rather sophisticated policy tools would create severe risks of further macroeconomic disturbances from the government—both because of imperfections in the political system and because governments may be more interested in stabilizing votes in the short run than the economy in a somewhat longer perspective. There is also a severe risk of distortions in the allocation of resources by way of deformations of the price system, in particular if policy interventions that are meant to be temporary will in fact be permanent. A heavy concentration of powers in a small group of civil servants and politicians may also arise.

In view of the experiences of economic policy so far, a *pessimist* or a *cynic* may even be tempted to say that the most severe difficulties of economic policy are imbedded in the political rather than in the economic system and that the main obstacle for a successful stabilization policy is, in fact, the government itself. Consequently, the best thing to do would be to avoid discretionary policies altogether rather than trying to make the interventions more sophisticated. He (she) can, of course, support this position by the reasonable assertion that the really dramatic macroeconomic disturbances during the last decade, and perhaps earlier as well, have been the result of government policies, rather than of instabilities in private behavior. In particular, it is difficult to avoid the empirical generalization that inflationary policies followed by restrictive, unemployment-creating actions have been a dominant macroeconomic feature.

*A careful optimist,* by contrast, may perhaps be willing to take some modest steps in the direction of amending aggregate demand management with more differentiated policy tools, for instance in order to influence the real wage rate and to increase factor mobility. A slightly more interventionist strategy would be to try some "semi-selective" management of demand and supply for rather *broad* components of aggregate demand and output —private consumption, fixed business investment, inventory investment, housebuilding, etc.

The *ultra-optimist* may be willing to go all the way to selective demand and supply management for different sectors and geographical regions.

Alternatives to experiments with some selective or semi-selective tools are either to reduce the ambitions in full employment policy somewhat, or to accept high and possibly accelerating inflation. It is, of course, also possible to reduce the "social costs" of macroeconomic instability, for instance by "bribing" firms to hoard "unnecessary" labor during recessions and by bringing about large-scale indexation of credit contracts and tax rates. I am then disregarding an extensive use of direct price and wage controls, which I do not have much faith in.[7]

However, the main message of the lecture has probably been that as we have two interacting systems, the political and the economic, we cannot control one with the other, but we must try to redesign them *both* to improve the stability of each. Most of my suggestions here for such redesigns have referred to the "intersection" of the two systems, as reflected by the policy instruments.

[7] I have no use in this lecture for the unclear concept "incomes policy."

The other suggestions for institutional reforms of the *economic system* have, I am afraid, been more wishful thinking than concrete proposals: to increase factor mobility and the flexibility of relative prices of commodities and factors, *hoping* that this will make both the rate of inflation more sensitive to reduced capacity utilization and less sensitive to increased capacity utilization. The really crucial issue in this context is, in my judgment, to make the labor market less inflationary and to prevent competing claims for income shares (or relative factor returns) from making stabilization policy unmanageable.

It is even more difficult to suggest changes in the *political system* that would improve macroeconomic stability and in particular make politicians follow what perhaps should be the Eleventh Commandment: "Thou shalt not *start* inflating!" However, features that may be singled out for consideration of reform are:

(1) the length of the election period, and the authority of the government to decide the time of election;[8]

(2) the choice between one-party government (or small coalitions) and broad coalitions for the purpose of limiting the "misuse" of short-term stabilization policy as an element in party-political competition;

(3) experiments with "depoliticization" of some policy agencies, such as the central bank;

(4) a more liberal use of discretionary powers of the cabinet without previous consent of parliament;

(5) a more critical attitude by economists, and citizens in general, to attempts by governments to buy votes by way of nonsustainable expansions;

(6) a new assignment of policy instruments and responsibilities between local, national, and international authorities.

The last point is perhaps the most important one. In particular, it is rather clear that the internationalization of the economic system during the post-World War II period has, in principle, considerably reduced the comparative advantage of the national government, relative to international coordination and to supernational organizations, in the field of stabilization policy. A good example is the need to control the supply of international credit, money, and liquidity. Another example is provided by the 1974–75 recession, when all countries seemed to hope for an export-led expansion, generated by expansionary policies in *other* countries!

To summarize, a solution of the problem of macroeconomic stability probably requires not only new and more elaborate policy instruments, as discussed above, but also some redesigning of both the economic and the political system—though, of course, without risking the two basic pillars of Western pluralism: the market system and political democracy. The present "crisis" in the Western economies is not, I think, mainly a "crisis in economics," though we economists have no doubt overestimated the stability of macroeconometric behavior functions. The main problem is not that we are unable to understand analytically what is happening, but rather that the institutional changes and the discretionary policies that are necessary for macroeconomic stability seem to be politically difficult to implement.

[8] For instance, a theoretical possibility would be to let the exact time of elections be determined by a random process.

# Marx and the Falling Rate of Profit

*By* JENS CHRISTIANSEN*

The renewed interest in Marxist economic theory during the past few years brought with it a renewed interest in what Marx himself called "the most important law of modern political economy," the "Law of the Tendency of the Rate of Profit to Fall."

K. Marx's own analysis of the laws of motion of capitalist development led him to the following formulation of this law. In the course of capitalist development there exists a tendency for live labor to be continuously replaced by dead labor. Capitalists replace workers by using more machinery. At the same time the increased productivity of the labor process lead to an increased amount of raw material and auxiliary material processed in any given hour of labor. Thus the amount of dead labor incorporated in the means of production (machinery, raw material, and auxiliary material) increases over time relative to the amount of live labor directly employed in the production process. Marx expresses this development in what he calls the rising organic composition of capital, i.e., an increasing ratio of dead labor to live labor. This development, Marx argued, would lead to a tendency of the rate of profit to fall over time. Thus, for him, this law is not a prediction at the level of appearances. Rather he claims that despite the existence of a number of counteracting forces, the tendency of the rate of profit to fall would assert itself as a continuous structural threat to the capitalist mode of production. On the one hand Marx clearly saw this tendency as a long-run development of the capitalist mode of production. It is, in this sense, directly related to the inherent dynamics of the process of capital accumulation. On the other hand he put great emphasis on linking up this tendency with short-run crisis phenomena. Marx saw crises as temporary breakdowns in the capitalist accumulation process. Yet at the same time he considered them to be a mechanism that recreates the preconditions for profitable capital accumulation. Crises are an inherent part of the continued reproduction of capitalism. "In the totality of this disorderly movement is to be found its order" (Marx 1933). One effect of crises is to reduce the rate at which real wages rise or even to cause a decline in real wages. Furthermore crises result in the devaluation of capital as well as its concentration and centralization. It is precisely these effects which allow the accumulation process to continue by reestablishing profitable investment opportunities.

Marx's own formulation of the law

* Stanford University. This paper is a byproduct of ongoing research with Bill Lunt which originated in the Political Economy Seminar at Stanford. Furthermore, I greatly benefited from comments on an earlier draft by Sue Bessmer, Michael Carter, Duncan Foley, Don Harris, Bridget O'Laughlin, Anwar Shaikh, Sandy Thompson, and Robert Williams. Unfortunately, because of limitations in time and space, I was unable to incorporate all useful comments and suggestions.

never took final form and contains a number of ambiguities. The different forces that influence the development of the organic composition of capital are never systematically put together. Nor is the relationship between the organic composition of capital and the rate of profit fully worked out. This situation has led to an ongoing debate over what the correct interpretation and application of the law is. Many of the contentions in this debate have led Marxists into wrong directions. At the empirical level the debate has centered primarily around the question of whether or not the organic composition of capital is indeed rising. At the theoretical level the argument has been predominantly concerned with the causes of a rising organic composition and the question of whether a rising organic composition will necessarily lead to a falling rate of profit. There seems to be enough progress on some fundamental points, however, so that we can eliminate much of the confusion that underlies many of these earlier debates.

The present paper will briefly deal with some of the criticisms of the law and with some of the inadequacies in alternative formulations that have been proposed. I shall try to show, in a very schematic way, that none of the existing formulations of the law have been fully adequate in what they are trying to do, viz. to lay bare the laws of motion of the capitalist mode of production. The second part of the paper will lay out a programmatic scheme for dealing with the issues. This scheme will be based on two aspects that Marx clearly identified in treating the falling rate of profit. The first relates to long-run trends in the process of capital accumulation. The second concerns the role of crises in the movement of the rate of profit.

## I. Criticisms and Alternative Formulations

In dealing with the existing Marxist literature I shall start with the question of whether or not the organic composition of capital is rising. Two extreme approaches have been taken. On the one hand it has been treated as a question the answer to which can be theoretically deduced from the definition of capital as self-expanding value.[1] This is clearly inadequate because it claims to understand existing material reality on the basis of idealist concepts created by the human mind. Such an approach is incapable of understanding changing historical structures.

On the other hand the question has been treated as a purely empirical problem. This is incorrect because the law is conceived at the abstract level of the capitalist mode of production. Thus all the links between this level of abstraction and the level of concrete reality have to be theoretically specified before an empirical investigation makes any sense. This involves questions of the accurate theoretical definition of the categories involved, their appropriate unit of analysis (e.g., national or world economy), and their historical specificity. The existing empirical studies fall short of most of these criteria. It is therefore not surprising that their results are contradictory and inconclusive. J. Gillman purports to show that the organic composition of capital for the *U.S.* economy has not shown any sustained tendency to rise since about 1920. Many Marxists and even more non-Marxist economists have shared that view. Victor Perlo, on the other hand, finds that the *U.S.* capital-labor ratio rises between 1929 and 1963. Shane Mage's results go into the same direction. However, he claims that the observed drastic fall "in the Marxian rate of profit for the U.S." is based to a major degree "on a substantial long-term decline in the rate of exploitation" (Mage, p. 3). A theoretical issue which also underlies the

[1] Some of the statements by David Yaffe and Mario Cogoy would fall into this characterization.

above empirical studies involves the definition of the organic composition of capital and its relationship to the rate of profit. Most Marxists have interpreted the organic composition of capital to be the ratio of constant to variable capital. The rate of profit (in value terms) is then a function of this ratio (the value composition of capital) and the rate of surplus value (the ratio of surplus value to variable capital). Both Joan Robinson and Paul Sweezy have pointed out that even if the value composition of capital increases with capitalist development, there is no reason to assume that this tendency cannot and will not be counteracted by a continuous increase in the rate of surplus value. Thus the development of the rate of profit over time is indeterminate, despite a rise in the value composition of capital.

This criticism is correct as long as we accept the interpretation that the value composition and the organic composition of capital are the same ratio. Once we take the organic composition to be the ratio of dead to live labor, then Marx's statement of the law is logically correct. This is easy to see. All we have to show is that the organic composition of capital is the inverse of the maximum rate of profit. In the case of zero wages the rate of profit becomes the ratio of surplus value to constant capital and the organic composition of capital becomes the ratio of dead labor (constant capital) to surplus value. Thus, if the organic composition of capital rises without limit, the rate of profit will eventually fall, no matter how much the rate of surplus value is going to rise.

This formulation of the law[2]—though logically correct—does not specify the actual mechanism by which changes in the organic composition lead to changes in the rate of profit.[3] A mathematical relationship that holds in the limit does not, in and of itself, imply any casual relationship between the two categories. Furthermore—as it stands—this formulation does not deal with the question of why the organic composition should rise. Some theoretical studies have tried to deal with these questions by analyzing why capitalists would introduce techniques with a higher organic composition of capital which could, at least potentially, lead to a fall in the rate of profit.[4] No unambiguous answer has been found. The reason for this is quite simple. It lies in a faulty methodology in these approaches. It is assumed that technical change comes about through capitalists choosing, on the basis of the profit criterion, among different existing techniques of production with a higher or lower organic composition of capital. In other words, the basic approach assumes given choice situations for capitalists. It thus neglects the more fundamental question of how these choice situations are generated by the historical development of social forces.[5] The whole point of Marxist social theory is to understand the determinants of these social forces, rather than to make predictions about the real world on the basis of mathematical relationships. The former can only be achieved through a concrete historical materialist analysis of the capitalist accumulation process based on an adequate theoretical conceptualization of the categories and relationships involved.

Before we turn to the issues concerning such analysis, one further criticism of the law must be considered. A correct treat-

[5] Exactly the same criticism applies to the voluminous bourgeois literature on the question of whether technical change has a labor-saving bias or capital-saving bias. For an interesting critique of this literature, see Nathan Rosenberg 1969.

ment of the transformation problem (between labor values and prices of production) shows us that in general the rate of profit in value terms does not equal the rate of profit in price terms (prices of production).[6] We are, however, interested in the latter rate because it is precisely in the prices of production scheme that an equal rate of profit for the economy as a whole gets established. Thus the appropriate conceptualization of the law has to be based on a prices of production scheme, with the overall organic composition of capital being a weighted average of the organic compositions of the different sectors, the weights corresponding to the proportions of direct labor used.[7]

## II. Accumulation and Crisis and the Rate of Profit

Where does all this leave Marx's law of the tendency of the rate of profit to fall? It has become clear that neither Marx's own formulation nor any of the subsequent approaches have been fully adequate. The two issues that have up to now dominated the literature are the question of whether or not the organic composition of capital is rising and secondly the causes for an increasing organic composition and its relation to the movement of the rate of profit. These issues are clearly central to the law of the tendency of the rate of profit to fall. However, the above critical evaluation of the literature has shown that these issues can only be understood within a framework that consists of two separate but closely interrelated parts. The first concerns the long-run development of the rate of profit within the capitalist accumulation process. The second involves influences of short-run crises on the movement of the rate of profit.

[6] See Ian Steedman, Alfredo Medio, and Christiansen and William Lunt.

[7] See Christiansen and Lunt.

Concerning the first part, there is a fundamental lesson that we can learn from a careful reading of Marx. An understanding of the long-run development of the organic composition of capital and of the rate of surplus value can only come out of a concrete historical analysis of the nature of technology and technical change under capitalism. That requires a careful analysis of the labor process and the changes it has undergone in the continuous process of concentration and centralization of capital which are integral parts of the process of capital accumulation. For Marx this process of accumulation is the particular form in which the dialectical interaction between forces and relations of production manifests itself under capitalism. Technical relations between people and nature, i.e., forces of production, always imply corresponding forms of social relations among people. Therefore we cannot analyze these two in isolation from each other. Any changes in technology will change the way people relate to each other and vice versa.

On the one hand there are many examples of how "complex technologies create internal compulsions and pressures which, in turn, initiate exploratory activity in particular directions" (Rosenberg 1969, p. 4). Technical imbalances between interdependent processes of production create strong stimuli for innovations. One example of such a technical imbalance would be Bessemer's development of a new process of steel production. Bessemer's

> . . . attention was directed to the subject of artillery by the outbreak of the Crimean War in 1854. He developed a new gun of superior power, capable of firing a heavy, elongated projectile. To his dismay, however, he concluded that the gun could not be safely fired if it were constructed of the standard cast iron employed in artillery pieces. The Bessemer process was the product of Bessemer's search for a super-

> ior metal which would make his newly designed gun practicable. [Rosenberg 1969, p. 7.]

Despite the fact that the initial push for a specific technical change in this example resulted from technical conditions, it should be stressed that such technical change will in general only come about and be maintained if it is compatible with the existing social relations, e.g., if it is profitable.

On the other hand there exist innumerable examples of technical change resulting in the first instance from the dynamics of social relations, the most drastic case in point being technical innovations initiated by capitalists as a response to working class threats against capitalist relations of production. The threat of the withdrawal of labor services through strikes has again and again been "a powerful force in directing energies in search for labor-saving machines" (Rosenberg 1969, p. 13). To provide just a few examples:

> The self-acting mule, the greatest invention of modern industry, put out of action the spinners who were in revolt. [Marx, n.d., p. 161]

> The invention of making gun barrels by means of grooved rolls is due to a Birmingham manufacturer of the name of Osborne. It was on the occasion of a strike of the barrel welders that he was led to make the experiment. [Goodman 1866, p. 389]

> The uncertainties which the supply of labor posed in the British gun-making industry led to the first large scale borrowing of American technology by the Old World. [Rosenberg 1969, p. 15]

Once again, despite the initial push this time coming from the social relations of production, these inventions were possible only because technology had reached a certain point prior to the invention.

Many of the above examples would suggest a development of technology which increases the technical composition of capital, i.e., the ratio of means of production (including in particular raw materials) in physical terms to the amount of labor employed. It is obvious, however, that a much more systematic historical and theoretical analysis is necessary. Within such an analysis one would also have to examine the crucial question of the development of productivity over time. A rising technical composition of capital does not necessarily imply an increase in the organic composition of capital. A careful reading of Chapters IV and V of the third volume of *Capital* clearly indicates that Marx himself was fully aware of the importance of certain trends that would lead to a decrease in the organic composition of capital. Such trends would include, for example, all measures that reduce the turnover period of capital.

Furthermore, we have to pay careful attention to the development of real wages as the third factor—besides the technical composition of capital and productivity—determining the organic composition of capital.

Marx himself attached special importance to the role of the capital goods sector in the generation of technological change.[8] Economies of scale are of particular significance in this respect.

H. Braverman's *Labor and Monopoly Capital* can serve as an important source for developing the necessary analysis of the labor process in the monopoly stage of capitalist development.

The second part of our analysis concerning the law of the tendency of the rate of profit to fall can also benefit greatly from a careful reading of Marx. In Chapter XV of the third volume of *Capital*, Marx emphasizes that the development of

[8] See Rosenberg 1976.

the rate of profit under capitalism is integrally linked to and cannot be understood separately from crises that interrupt and simultaneously recreate the conditions for the process of capital accumulation.

The accumulation process that I have talked about above is certainly not seen as a smooth process by Marx. Its dynamics come directly out of the basic contradiction between capital and labor in their struggle over the control of the production process and the appropriation of the final product.

This struggle will at certain times lead to the closing off of profitable investment opportunities at least for the weaker capitalists. At such a point spending of capitalists and consequently of workers declines. Thus the system as a whole will be confronted with insufficient demand. Not all commodities produced can be sold and the crisis of accumulation manifests itself as a realization crisis. This will lead to bankruptcy and unemployment. The consequence will be further concentration and centralization of capital and simultaneously a slow-down or even a decline in real wages. Inefficient capital will get destroyed in the process. All of these developments will eventually recreate the conditions for profitable capital accumulation by raising the rate of exploitation and lowering the organic composition of capital.

This outline is indeed extremely sketchy. Serious work remains to be done on the Marxist theory of crisis. In particular the role of the money and credit system within the crisis is in need of further systematic analysis.

### III. Conclusion

The above very sketchy review of the literature on Marx's law of the tendency of the rate of profit to fall has shown us that—at present—no satisfactory formulation of this law exists. However, Marx's own ideas on this subject still seem to provide us with extremely useful insights into the capitalist accumulation process and its concomitant crises.

# Stagnation, Instability and International Competition

*By* RAFORD BODDY AND JAMES R. CROTTY*

Significant economic events typically find their reflection in theoretical controversies. The crisis of *U.S.* and world capitalism is no exception. Over the last several years there has been a resurgence of interest in Marxian crisis theory, that part of Marxian theory which deals with the inevitable impediments within capitalism to prolonged growth. Obviously, crisis, depression, and recovery are integrally related. In this essay, we are particularly concerned about the nature of recovery because we believe that a correct understanding of its dynamics is central to the development of a correct theory of the laws of motion of modern capitalism.

For our purposes, theories of the recovery can be divided initially into those which imply that endogenous forces unleashed in the crisis and depression eventually generate a strong recovery and those which deny that such endogenous forces exist. Associated with the former group would be such business cycle theorists as Arthur F. Burns and Wesley C. Mitchell as well as those Marxists, including ourselves, who believe that the depression eventually recreates a potential for profit-making sufficiently strong to renew the accumulation process. The latter group would seem to include neo-Keynesian disequilibrium theorists such as Robert Clower and Axel Leijonhufvud who have critically analyzed unemployment but have as little to say about the way in which the economy gets out of a crisis as they do about how it gets in. However, the most important set of theorists who deny the possibility of endogenous recovery are the stagnationists. In the Marxist tradition, stagnation theorists have been extremely influential. They include Michal Kalecki, Paul Baran and Paul Sweezy—justifiably ranked among the most eminent political economists of the modern period—and J. Steindl whose seminal work of 1952 is again in press.

Because it has provided an explanation of the workings of modern capitalism consistent with such important developments as the Great Depression, the immense growth of the state sector, and the high unemployment of the late 1950's and early 1960's, the monopoly-based neo-Marxist theory of stagnation is undoubtedly attractive. But, while the theory provides useful insights into the historical process by which monopolization creates certain impediments to expansion and exacerbates the dislocations of depression, its denial of the long-run recovery potential of modern American capitalism is seriously misleading.

In this exploratory essay we briefly review the tenets of stagnation theory, point to some of its main weaknesses, and examine its consistency with post-World War II economic developments. To anticipate the principal conclusion, we find that secular changes of the productive forces in the international sector have led to increasing competition and intercapitalist rivalry and thereby have gradually re-

* American University and University of Massachusetts at Amherst. Data references have been omitted due to space limitations but are available on request.

duced the explanatory power of the theory of chronic stagnation.

## I. Tenets and Problems

The central proposition of the most influential variant of neo-Marxian stagnation theory is that the rising surplus in the monopolized core of the economy cannot be absorbed by the private sector. (On the concept of the surplus, see Baran and Sweezy, pp. 9–10.) In the absence of increased state sector stimulation (dramatically evident in wartime) or exogenous, epoch-making innovations, such as the growth of the railroads or the auto industry and its derivative sectors, monopoly capital, it is argued, should be characterized by high and rising unemployment rates, decreasing rates of capacity utilization, ever weaker expansions, longer contractions, and a rise in the percentage of resources devoted to wasteful, nonproductive activities such as the sales effort. Correspondingly, given strong exogenous stimulation, monopoly capital should exhibit dramatically rising levels of profit and cash-flow, an increasing rate of profit, and a corresponding decline in labor's share of income. Since the state has accepted responsibility for overall economic performance, there should be a tendency for the state sector to grow relative to the rest of the economy.

Among Marxists, the most strongly questioned part of the theory has been the tendency of the surplus to rise. This is natural enough since Baran and Sweezy themselves note that the law immediately invites comparison with the classical Marxian law of the falling tendency of the rate of profit. Data on markups at given levels of capacity utilization presented by Baran and Sweezy (p. 84) support their formulation. On the other hand, more recent data on the same series presented by J. Blair (p. 641) provides evidence to the contrary. A corollary of the rising surplus is the ability of the corporation to raise prices during periods of high demand by an amount sufficient to offset or exceed any increase in unit labor costs. As evidenced in the data of the postwar period, however, labor has been able to increase its share in the latter part of such periods (see Boddy and Crotty). This evidence casts doubt on the alleged tendency of the surplus to rise.

We are equally concerned with the validity of the stagnationists conclusion that modern capitalism has no significant long-run endogenous outlets for that surplus. As the stagnationists see it, the fierce drive of the capitalist to accumulate and grow is in no way diminished by oligopolization. Yet, the surplus is presumed to be effectively bottled up by the decline in profitable outlets. The corporation, it is argued, does not want to spoil its own market through expansion and is hesitant about investing outside of its industry. However, it would appear that there are many channels whereby any excess surplus can and does find outlets. The surplus, as noted by the stagnationists, can be thrown into the sales effort. The corporation can integrate vertically. It can invade other product markets, particularly in the competitive sectors, directly or through conglomerate mergers. It may expand geographically within the country or, as in recent decades, internationally. Indeed, each of these outlets has been cited by Sweezy himself. And, as monopoly firms pour capital and labor into the competitive sector, the ensuing expansion feeds back into the monopoly sectors. Moreover, the financial sector, though far from frictionless, does move surplus to areas with profitable investment opportunities. Each of these outlets has been aggressively utilized by the corporations in the postwar period.

The fact that *U.S.* and international capitalism have been characterized by

substantial growth in the last half century has obviously not escaped the notice of such astute observers as Kalecki, Baran and Sweezy. Rather, the growth has been primarily attributed to wars and epoch-making innovations assumed to be exogenous. But, if the law of capitalism remains "accumulate, accumulate," then there is a perpetual tendency to revolutionize the means of production, and pressures toward path-breaking innovations are built into the system.

The question of what is and what is not to be taken as exogenous is, of course, a long-standing problem. For Marxists, even the surplus absorption of wars has a strong endogenous aspect. As Myron Sharpe has aptly remarked, "Why can we not argue that the main tendency of monopoly capital is major innovations and wars, these being interrupted at times by abnormal periods of stagnation?" (P. 46.) The major point we wish to emphasize is that monopoly capitalism is still capitalism. The drive to grow, to accumulate, to take advantage of and *create* profit-making opportunities is not dulled. While the growth of oligopoly has created the likelihood of more severe crises and depressions as explained by the stagnationists, capitalism has not been shorn of its endogenous expansionary capabilities.

## II. Theory and Reality: The Mid-1950's Through the Early 1960's

For a significant period of time during the post-World War II era, particularly from 1956–57 through 1962–63, the central deductions of stagnation theory were in large part consistent with the empirical evidence. Corporations were able to finance most if not all of their expenditures on physical assets out of internally generated funds. Expenditures on the sales effort and planned obsolescence were clearly rising. Moreover, the economy could be sensibly described as stagnant. From 1958 through 1963, the rate of unemployment averaged almost 6.0 percent, fluctuating from an annual low of 5.5 percent to a high of 6.8 percent. From 1956 through 1961, the average annual rate of growth of real *GNP* was only slightly in excess of 2 percent.

The stagnationists associate a large government sector with the absence of depression and a sluggish economy with the absence of active government stimulation. To what extent can these particular conditions of stagnation be attributed to the alleged need for greater and greater government stimulus in the face of an increasing stagnationist tendency? In the context of this question, it is important to distinguish between the failure of the government to positively stimulate the economy—a "neutral" policy—and a policy of active and deliberate restraint. In fact, government policy in this period falls into the latter category. Real purchases of goods and services by federal, state and local governments dropped substantially in 1954 and moderately in 1955. In turn, they were almost constant from 1958 to 1960. At the federal level, where spending is associated with conscious macropolicy objectives, real purchases were lower in 1961 than in 1954. The high employment budget had been in deficit from the third quarter of 1951 through the second quarter of 1954, and had obviously contributed to the boom of that period. However, it was in surplus from the third quarter of 1954 through the third quarter of 1965, with an especially large surplus in 1956–57 and 1960–61. As to monetary policy, we note that total member bank reserves were lower in 1963 than they had been in 1952. Within the period 1954 through 1960, we find that only in 1958, in the midst of a severe contraction brought on in part by restrictive monetary policy, did the monetary base expand at a rate appreciably greater than 1.5 percent per annum.

Why did the policy makers feel compelled to hold down a supposedly stagnating economy? We believe that the evidence is consistent with the hypothesis that macropolicy from the mid-1950's to the early 1960's was kept firmly restrictive in pursuit of two objectives, both of which would have been jeopardized by the normal process of endogenous economic expansion in the absence of such governmental restriction. One was a desire to prevent the inevitable "excesses" endemic in capitalist expansions, such as rising wages, labor militancy, and inflation, from eroding profits, thereby creating the preconditions for a major contraction. The other was a desire to protect the crucial international institutions under *U.S.* control as well as the privileged reserve currency status of the *U.S. dollar* from those pressures generated by sustained expansion which it is clear in retrospect could have led to a rapid decline in the international position of the United States. That macropolicy was deliberately kept restrictive in order to achieve such objectives is made clear in the studies by G. Bach and H. Stein of the history of macropolicy making in this era. The sluggish behavior of the economy during the period 1956–63 therefore cannot be taken as prima facie evidence of the lack of an expansionary dynamic of the private sector.

## III. Theory and Reality: The Last Decade

Whatever attraction stagnation theories may have as an explanation of the experience of the 1950's and early 1960's, an examination of the record of the past decade casts doubts on their long-run adequacy. Provided that sufficient growth in aggregate demand is maintained, it follows in the logic of the theory that the industrial corporate sector should attain rising profits, a growing profit share, and an increasing flow of internally generated funds. Under the expansionary macropolicy of the early 1960's and the military spending of 1965–68, aggregate demand was sustained at a high and increasing level for most of a decade. Yet, starting in 1965 corporations experienced falling rates of profit and were increasingly forced into the credit market to finance accumulation. In nominal terms, internally generated funds of nonfarm, nonfinancial corporations were virtually stagnant from 1966 through 1969, while in real terms they declined substantially. Corporate indebtedness grew dramatically. Now, while the accumulation of consumer and government debt fits comfortably into monopoly-based stagnation theories, *eroding profit margins and accelerating corporate debt in periods of high demand do not.* In like manner, stagnation theory seems singularly unfruitful as a framework within which to analyze the changes which have occurred in the relationship between banks and major nonfinancial corporations. The increasing dependence of major corporations on banks for their financing, well documented by H. Magdoff and Sweezy, seems to move us beyond the confines of stagnation theory.

## IV. The Rise of International Competition

To fully understand the partial empirical success of stagnation theory in the 1950's and its inadequacies during the last decade, we believe that one must include the international sector in the analysis. For this sector has inevitably become an arena of increasing capitalist contention, competition and rivalry. As is now becoming universally acknowledged, profound changes have occurred in the international system in the past 25 years. Parts of the world have been forcibly removed from the direct control of the major capitalist powers. The financial arrangements of Bretton Woods, which included the privilege of *U.S.* seigniorage, have broken

down. There has been an as yet unreversed decline in *U.S.* control over formerly cheap supplies of energy and raw materials. But the most important secular change has been the end of the monopoly power of the United States within the international capitalist system and the concomitant rise of Japan and the European Economic Community countries, especially West Germany, as serious economic and political rivals of the United States. The inability of the United States to suppress conflict and to enforce the international "rules of the game," originally written to maximize its own advantage, has fractured the stability of the international capitalist system.

Over the last fifteen years, the resurgent and technologically advancing industries of Japan and West Germany have subjected *U.S.* corporations to increasingly tough competition in international trade, investment, and the struggle for control of raw materials. From 1960 to 1972, exports in constant dollars grew at 6.0 percent for the United States, 9.7 percent for West Germany and France, and 16.7 percent for Japan. Of course, these trends accelerated appreciably during the Vietnam War. Lest this all be dismissed as an exercise in exponents, we point out that by the terminal year the value of Japanese and West German exports were 55 percent and 95 percent as large, respectively, as those of the United States. The decline in American power and the dilemma it presents for American corporations and policy makers have been succinctly set forth by C. Fred Bergsten in a recent issue of *Foreign Affairs*:

> Not long ago the United States was virtually the sole source of large chunks of investment capital, technological know-how and marketing skills. Not long ago, security considerations devolving from the cold war enabled the United States to dominate its allies, most small countries and the international rules and institutions which governed world economic relations. Now, however, . . . (i)ncreasing numbers of European and Japanese companies offer formidable competition for American multinationals . . . With the onset of detente, host countries, large and small, no longer fear to cross the United States by challenging U.S. based firms and the economic environment that helped them flourish in the 1950's and 1960's. [p. 138]

In this essay we are concerned with the implication of these changes in the international sector on the dynamics of the *U.S.* economy, especially their impact on its potential tendency toward stagnation. The inevitable resurgence of international competition raises the following question: *Will an economy characterized by a tendency toward stagnation because of the oligopolization of its major industries develop serious countertendencies as that economy becomes enmeshed in increasingly severe international competition?* Certainly increasing competition for raw material and markets implies that costs may not be so easily reduced, nor profit margins so easily protected. In like manner, if *U.S.* corporations fail to invest and expand in order to avoid spoiling the market, others will encroach on their market share. International competition means pressure to trim down corporate fat and muscle-up the production process. Significantly, many of the industries, such as autos and steel, which epitomized the oligopolistic market structure at the heart of stagnation theory are now those under most intense international attack.

Many of the "confusing" phenomena of the last decade are more easily understood once we take increasing international competition into account. Increasing competition helps to explain why prices failed to rise sufficiently to cover the increased unit labor costs of the late 1960's. This, in turn, helps explain the precipitous

decline in profit margins and the increasing need for external finance. There are also a number of important recent developments in the realm of government policy making which are quite consistent with a resurgence of international competition. The concern with "capital shortage" and the drive to increase the percentage of *U.S.* output channeled into investment up to the level achieved by *U.S.* competitors, the attempt to reverse the decade-long decline in labor productivity, the pressure to halt or reverse the growth of public employment and welfare programs, and the increased interest in economic planning all seem to be more easily associated with increasing competition than with a perspective of chronic stagnation.

## V. Conclusion

Rooted in the reality of the growth of the giant corporation and the continuous rise of monopoly power, neo-Marxist theories of stagnation have raised valid and interesting questions about the development of additional impediments to sustained expansion and, perhaps more importantly, about the increased potential severity of crises and depressions. Our quarrel is with the concept of chronic stagnation and its denial of the prospect of eventual recovery and subsequent expansion.

We agree with Baran, Kalecki, Steindl and Sweezy that depressions have a tendency, in the absence of state intervention, to be more prolonged in a system of monopoly capitalism. But for that very reason, monopoly capitalism has a tendency to generate even more powerful bursts of expansion and accumulation. In turn, it is the very strength of the accumulation process which creates those excesses endemic in capitalism which eventually rupture the expansion, making crises inevitable and recessions and depressions functional. It is the potential for overexpansion which had led macropolicy-makers to restrain the economy as often as they have stimulated it. Currently, in spite of the extremely high levels of unemployment and unused capacity, macro policy-makers are determined to prevent the mild expansion we are experiencing from generating too much momentum. (For an analysis of the macropolicies of the past decade and a discussion of policy prospects, see Crotty and Rapping.)

Thus, the question at issue is not whether the working people of America, under existing capitalist institutions, can avoid the unemployment, insecurity, and waste of recurring recessions and depressions. The question is the underlying mechanics of crisis and recovery, in particular the very possibility of the latter. We reject the concept of perpetual depression as the natural state of monopoly capitalism, and do not look to monopoly based stagnation theory for the key to understand the origins of the recent crisis of *United States* and world capitalism.

# International Crisis and Politicization of Economic Activity

*By* Daniel Luria and Arthur MacEwan*

The crisis in the international operation of *U.S.* business has developed from basic changes in world power relations. The decline in the *U.S.* trade position, the breakup of the capitalist world's monetary system, the formulation of new policies toward the Soviet Union and China, the rising strength of the major oil-producing nations, and the final defeat of *U.S.* aggression in Indochina constitute a chronicle of the changing world order.

The international crisis is working in combination with domestic events to produce a far-reaching impact on the nature of economic, social, and political relations within the United States. In this paper, we focus on two aspects of that impact. First, the international crisis is contributing to the development of a wider and qualitatively new role for the government in economic affairs; there is an intensification of direct government involvement in foreign economic affairs and a new emphasis placed on supply or cost factors in domestic fiscal policy. Second, and in part related to this changing role of government, the international crisis is effecting an intensification of class struggle within the United States.

This paper is intended as part of a Marxist interpretation of the current economic crisis. In this context, we would like to call attention to four main themes that underlie our analysis: 1) the fundamental unity of capitalism as a world system, (2) the class nature of the capitalist state, (3) the development of crises out of the basic contradictions of the capitalist production process, and (4) the interaction between changes in economic relations and class struggle.

## I. The Crisis and Shifts in International Business Activity

Ironically, the increased instability of international affairs has been accompanied by a heightened intensity in *U.S.* business's foreign activity. During the 1970's, the rate of growth of direct foreign investment has maintained its high level of the 1960's. The growth of both imports and exports has substantially outstripped the increase in *GNP*.

There are two explanations for this rise in international activity in time of crisis. First, the crisis internationally is bound up intimately with the domestic economic dislocations which have driven down profit rates within the United States significantly over the past decade. Consequently, the search for profits abroad through both trade and investment has assumed a new urgency. Second, the changed international environment has been characterized by the increased competitiveness of foreign manufactured goods in *U.S.* markets, as well as by a sharp rise in the prices of petroleum products. Both have contributed to an expansion in imports; and, in an effort to alleviate the consequent *U.S.* trade deficits while also maintaining the value of the dollar, the government has promoted exports with unparalleled vigor.

It is in examining some of the particu-

* Graduate student, University of Massachusetts–Amherst, and Visiting Associate Professor of Economics, University of Massachusetts–Boston, respectively.

lars of these aggregate responses to the crisis that the most interesting implications come to light. We shall look, in turn, at import shifts, export shifts, and changes in the pattern of direct foreign investment. Each of these is associated with a qualitative increase in the government's direct involvement in economic affairs.

### *A. Import Shifts*

Over the past several years, accompanying the dramatic rise in total imports, there have been two sorts of shifts in the composition of imports. The first of these is the increasing importance of manufactures in the import bundle. In the 1960-64 period, 46 percent of merchandise imports to the United States were manufactured goods; in the 1965–69 period, the figure rose to 59 percent; and for 1970–74, it stood at 63 percent.[1]

This first change in import activity provides an accounting of the process by which the other capitalist nations have overcome the post-World War II industrial supremacy of *U.S.* business. While the relative advance of those nations had been on the economic horizon for a number of years, slow productivity growth in the United States during the late 1960's and the associated inflation led to a marked increase in the pace of that advance.

The second major shift in the composition of *U.S.* imports has been the higher share represented by petroleum and petroleum products. As a share of total imports, crude materials and fuels—mostly oil—fell from 28 percent in the 1960-64 period to 20 percent in the 1965–69 period, and then dropped still further to 16 percent for 1970–72. But for 1973–74, crude materials and fuels rebounded to 26 percent of total imports.

The higher share of crude materials and fuels has been brought about largely by the jump in the price of petroleum, rather than by any increase in the quantity of petroleum imports. The price increase has, of course, been the result of a significant restructuring of world power relations. With its developing defeat in Vietnam and the concomitant weakening of the *U.S.* economy, the government was in no position in 1973 either to discipline the oil-producing nations or to bring about a common response on the part of the major oil-consuming countries.

The combination of the long-term increase in manufactured imports and the recent sharp rise in the value of petroleum imports has presented the United States with severe difficulties.[2] At the very least, these changes have contributed to the destruction of *U.S.* hegemony in world capitalist affairs. The dollar basis of the international monetary system, for example, has been torn apart by the relative growth of foreign business strength. This has meant, and will likely continue to mean, substantial losses for *U.S.* businesses. However, the *U.S.* government has taken strong action in an effort to dampen the impact of rising imports. (In the absence of such government involvement, there would be an even further decline in the value of the dollar and an even greater transfer of real income from the United States to foreign countries.)

At least three sorts of actions have been taken by the government. The first and most visible of these has been the recent attempt to formulate a comprehensive national energy program. While we are not

[1] In 1973 and 1974, the huge increase in the cost of oil imports dampened this trend in import composition. If we look only at the three years 1970–1972, manufactures accounted for 67 percent of total imports.

[2] To a degree, the international petroleum situation has helped to offset the relative *U.S.* decline with regard to trade in manufactured goods because the other capitalist nations have been hurt more seriously by the rise in oil prices. Nonetheless, while the "energy crisis" has meant a relative setback for European and Japanese business, it has not halted the continuing challenge to their *U.S.* competitors.

concerned here with the details of the conflicts surrounding this attempt, we do wish to note that, regardless of what particular policy emerges, that policy and the process of its formulation will have involved a high degree of government participation in the energy sector of the economy.

The second consequence of the rising importance of oil imports has been an effort on the part of government and the oil industry to diversify sources of imported oil. Nigeria has quickly become one of the largest suppliers of imported petroleum to the United States. Indonesia and Angola (the latter still under Portuguese control in this period) also became important suppliers in the early 1970's. These developments could hardly have taken place without a concerted effort by Washington to promote "friendly" regimes in these nations. While the involvement of the *U.S.* government in helping to obtain and protect foreign sources of supply is hardly new, the oil crisis has forced an intensification of government concern. As a tactic in combatting petroleum supply difficulties, though, increased government involvement should be seen as merely changing the nature of the problem: the potential political conflict arising from the situation in Angola, for example, is hardly less serious than the oil crisis itself.

### *B. Export Shifts*

The third area of government response to the problem of rising imports has been a vigorous policy of export promotion. The trade deficit which first appeared in 1971 came as no surprise since it merely represented an extension of trends established during the preceding several years. Accordingly, it is also not surprising that plans for responding to the deficit were already in the making.[3] Washington foresaw the relative decline in the export potential of the *U.S.* manufacturing sector and, as part of the remedy, laid out a program for the expansion of *U.S.* agricultural exports. The two central aspects of the program were:

(1) the negotiation of special arrangements with foreign governments. This aspect of the program has been carried out by means of such expedients as the Soviet grain deals and pressure on European governments to adjust trade regulations in favor of *U.S.* agriculture.
(2) the structuring of domestic prices to favor agricultural production. This aspect of the program was set in motion through the wage-price controls which took effect in August 1971. Raw agricultural products and exports were explicitly exempted from controls, encouraging the growth of farm output and its sales in foreign markets.

The program worked. The value of agricultural exports tripled from 1970 to 1974. Between 1966 and 1971, agricultural goods accounted for 18 percent of *U.S.* exports; for the period 1973, 1974, and the first half of 1975, the figure has been 23 percent.

The second part of the export-promotion strategy consisted of a policy of vigorous sales of armaments to foreign governments. *U.S.* arms sales abroad climbed from \$1.7 billion in fiscal 1971 to \$9 billion in fiscal 1975, or from 4 to 10 percent of total exports.

The intimate relation of the *U.S.* government with arms producers in the promotion of military sales abroad hardly needs documentation here. The govern-

[3] This foresight took the form of a report, *United States International Policy in an Interdependent World*, prepared by a special Presidential Commission and published in 1971. For a discussion of the report and of the "planned" nature of the rise in food prices, see Boddy and Crotty.

ment both finances weapons research and development costs and facilitates marketing as part of the normal process of foreign policy.

We have a situation, then, in which the two main thrusts of *U.S.* export expansion—agriculture and arms—have been implemented with the planning, sponsorship, and active intervention of the government. Though government involvement in foreign trade is nothing new, the degree and importance of that involvement in response to the current crisis suggest a qualitative change in the relationship of government to the economy.

### *C. Investment Shifts*

As with trade, government involvement with the process of foreign investment is not new. Yet here, too, current developments point to increasing intensification of that involvement. In particular, there seems to be a shift toward more manufacturing investment in certain underdeveloped countries. The evidence on this point is still fragmentary and can only be taken as suggestive. The share of total direct foreign investment classified as manufacturing in "developing" countries has crept up from 7 percent in 1966 to 8 percent in 1974. However, because the dollar has declined in value relative to the currencies of most advanced countries but has remained more stable relative to those of nations in the "developing" category, the real shift toward the "developing" nations has surely been greater than these figures indicate. In certain countries, the recent increase in manufacturing investment has been very large. Total *U.S.* manufacturing investment in Brazil, for example, jumped from $2.03 billion in 1973 to $2.50 billion in 1974; and in Mexico, from $1.80 billion to $2.15 billion.

This apparent new growth of manufacturing investment in certain underdeveloped countries is a direct consequence, on the one hand, of rising unit labor costs in the advanced capitalist nations and, on the other hand, of the development of large and "well-controlled" work forces in certain poor countries. South Korea and Brazil are among the oft-cited examples, the latter recently described by *Business Week* as a country in which "More than a decade of authoritarian military rule has created a climate of political confidence and virtually eliminated labor problems. . . ."

The trouble with military regimes, though, is that even the most stable among them require continuous injections of military support from Washington. And often they are not so stable. Accordingly, as with the attempt to diversify sources of oil supplies, current developments in the foreign investment field are tying the *U.S.* government ever more firmly to policies of manipulation and intervention throughout the world.

## II. The Crisis and the Domestic Role of the State

The current international crisis has not only led to intensified government involvement in the international activity of *U.S.* business. It has also brought about a changing government role in domestic affairs.

The changing role of the government is most usefully interpreted in the context of the central contradiction surrounding the value creation and realization process in capitalist society. In its efforts to maximize surplus-value, business is hemmed in on two sides. On the one hand, failure to suppress wage costs directly and immediately cuts into surplus-value. On the other hand, success in suppressing wages undermines the expansion of effective demand, the basis for the realization of surplus-value.

During the long expansion of the 1950's and 1960's, the manifestation of this con-

tradiction was averted by two sets of circumstances. First, the government contributed heavily to the maintenance of high levels of effective demand. Second, low fuel and food costs, both made possible by *U.S.* hegemony in international affairs, allowed business wage costs to remain low. Moreover, government spending to expand demand combined with limited foreign competition to make possible the simultaneous growth of profits and wages.

But by the late 1960's, the expansion of government spending had contributed, in two ways, to the undermining of profit rates (and rates of surplus-value). First, unemployment had dropped to relatively low levels, increasing the bargaining power of labor and making for a shift in factor shares away from capital and toward labor. Second, expenditures on welfare, unemployment compensation, and other social services had exerted upward pressure on wage rates. As the crisis in international affairs has simultaneously increased food and fuel prices and increased foreign competition, the problems created by the expansionary policies of the 1950's and 1960's have become more severe.

A partial remedy is being sought in limiting the size of the government deficit. However, given the present depressed state of the economy and the fear of another downturn in the near future, the potential for reduction of the deficit is severely limited. It seems likely therefore that greatest attention will be given to developing a fiscal strategy that will maintain aggregate demand while placing a minimum of upward pressure on wages.

On the spending side, this strategy calls first for a reduction in government spending on social service programs. Cases in point include the administration's recent efforts to cut back food stamps, government job creation, day care and child nutrition programs, and other aspects of health and education support. Federal action is being coupled with state and local efforts around the country to cut back on welfare payments and aid to the unemployed. Even the nature, if not the level, of military expenditure is likely to be affected, with more emphasis on research and development, for example. The tax structure implicit in the government's developing strategy hardly needs to be stated: there will certainly be an effort to shift the burden away from capital toward labor.

Changes in policy orientation on the scale of those currently being undertaken require thorough ideological support. The barrage of propaganda concerning a "capital shortage" is a central element in forging the necessary ideological climate. To be sure, the "capital shortage" is not simply fictitious; the international and domestic crises have meant real, structural changes in the economy affecting production costs. The issue, however, is who will pay the new costs. Were the "capital shortage" propaganda to work, labor would accept the shifts in government fiscal policy and would acquiesce at the bargaining table.

The "capital shortage" ideology provides a lever for dealing with a number of problems. For example, it seems to be working well as a guiding principle for handling the New York City crisis as well as other local fiscal difficulties. In New York, business and government have united (in spite of sectarian tactical disputes) around a program which would accomplish at the local level, and in an exaggerated manner, what the federal budget would accomplish at the national level. Gains won by labor in contract struggles and in political battles would be sharply cut back by any of the proposed "assistance" programs.

In sum, the "capital shortage" rhetoric is a major part of the ideological cam-

paign at the center of an intense political and economic offensive currently being waged by business interests in response to the economic crisis.

## III. Conclusions

The business offensive is, however, likely to generate a response. There is little reason to expect labor and various social action movements to abandon their militance simply because business is making threats. The bureaucratic nature of organized labor may serve to dampen militance. But the power of union bureaucracies has been based on an ability to deliver the goods, and now that ability has been severely undermined.

Furthermore, labor's response to the current business offensive may take on some qualitatively new aspects. The depoliticization of working class struggles in the United States has depended on more than a steadily rising standard of living. Another major factor has been the ability of the government to maintain an illusion that it plays a class-neutral role in economic affairs. The crisis itself has interrupted the advance of living standards. And, as we have argued in this essay with emphasis on international affairs, the government is being forced by the crisis to take a more direct and active role in the economy. It is thus becoming less and less tenable for the government to retain its class-neutral image. Accordingly, we think it likely that as working people develop a response to the current crisis, their actions will become increasingly politicized and class conscious.

# THE LAST GREAT DEPRESSION AND THE PRESENT ONE

# Lessons for the Present from the Great Depression

*By* PETER TEMIN*

The economic contraction that started in 1929 was the worst in history. Historians have compared it with the downturns of the 1840's and the 1890's, but the comparisons serve only to show the severity of the later movement. In the nineteenth-century depressions, there were banking panics, deflation and bankruptcy in various proportions. But there is no parallel to the massive underutilization of economic resources in the 1930's.

Given the magnitude and importance of this event, it is surprising how little we know about its causes. The reactions of people to the Depression, the policies undertaken during the Depression, and the effects of the Depression have all been the objects of extensive study. But the economic collapse itself has suffered a form of intellectual neglect. Too long ago to be part of the study of the current economy, too recent to be included in most courses in economic history, too complex to be explained simply, economists have—with a few prominent exceptions—left the study of the Depression to others. The inevitable result has been a neglect of the economic aspects of the Depression. While economists have advanced a variety of hypotheses to explain why depressions can take place, little attention has been given to the explicit application of these competing theories to the biggest depression in history.

One reason, often and correctly given for the magnitude of the Great Depression, is the absence of a concerted expansionary macroeconomic policy between 1929 and 1933. The monetary and fiscal policies that we now think could have been effective in moderating or eliminating the contraction were not used to any perceptible extent.[1]

But the question of what macroeconomic policy would have worked is only one question that can be asked about the Great Depression. It is of considerable interest also to know what happened to make such a corrective policy desirable.[2] What happened in the years around 1929 that (in the absence of offsetting govern-

* The research on which this paper is based was supported by the National Science Foundation. The paper has benefited from the comments of Rudiger Dornbusch, Stanley Fischer, and Frederic Mishkin. All are to be thanked. None are to be implicated in the views expressed. The views expressed here are the author's and do not reflect those of the Dept. of Economics or the Massachusetts Institute of Technology.

[1] For the failure of monetary policy to be used, see Friedman and Schwartz, 1963a. For the failure of fiscal policy, see E. Cary Brown, 1956. M. R. Norman, 1969, argues that a successful counter-cyclical fiscal policy would have had to exceed greatly the scale of anything even contemplated in the 1930's. Of course, the negative argument that macroeconomic policies were not used is hardly the same as the positive argument that these policies would in fact have been effective. This assertion is difficult, possibly even impossible, to prove, and the debate about it revolves on questions about the structure of the economy rather than the occurrence of specific historical events.

[2] This is the question I have addressed in Temin, 1976.

ment policies) led to the historically unique events of the 1930's? While this question is different from the question of what policies are appropriate for curing depressions, it is not unrelated, as the work of Milton Friedman and Anna Schwartz shows.

Friedman and Schwartz's classic *Monetary History of the United States* forms the base of an argument that movements of income have historically been caused by changes in the stock of money, which in turn are caused by a variety of exogenous factors.[3] The *Monetary History* documents the last step of this argument, from which the other steps are derived.

Upon examination, however, the *Monetary History* turns out to be an account of the supply of money. Friedman and Schwartz never acknowledge the existence of the identification problem implicit in any attempt to partition changes in a quantity into changes in the supply and changes in the demand. Instead, they discuss the supply of money and ignore the demand—a procedure that can only be justified by the assumption that changes in the stock of money were attributable almost entirely to shifts of the supply curve. This proposition, which the *Monetary History* appears designed to prove, is instead an assumption on which the analysis of the book rests.[4]

For instance, the *Monetary History* asserts that the stock of money fell in the early 1930's because of an autonomous fall in the supply of money. The fall in the supply was caused in the first instance by a decline in Federal Reserve credit outstanding in 1930, but far more importantly by the effects of the banking failures that started in late 1930. The fall in the supply of money induced a movement along the (stable) demand curve for money—that is, a decline in income and interest rates—to equilibrate the money market.[5] The fall in income therefore was a result of the autonomous factors decreasing the supply of money.

Because of the incompleteness of the book's argument, however, there is nothing in the narrative of the *Monetary History* to refute the following completely different story: Income and production fell after 1929 for nonmonetary reasons. Since the demand for money is a function of income, the quantity of money demanded fell also. The money market was equilibrated by the fall in the stock of money following the bank panics, but these panics did not in any way cause the decline in income.[6]

It is not easy to resolve the implicit identification problem and choose between these two stories, and I have tried a variety of approaches. Space precludes anything more than a brief mention of my conclusions here as they are fully reported elsewhere (see Temin, 1976). I found that it is harder to discriminate between these two stories than one might imagine from the intensity of the debate among macroeconomists, but that there is no evidence of any effective deflationary pressure from the banking system between the stock-market crash in October 1929, and the British abandonment of the gold standard in September 1931.

As mentioned at the start of this discussion, this disagreement among histori-

[3] Friedman and Schwartz, 1963a. The argument is implicit in the *Monetary History*, but made explicit in Friedman and Schwartz, 1963b, and Friedman and David Meiselman, 1963.

[4] This interpretation of the *Monetary History* is extensively documented in Temin, 1976, Chapter II.

[5] Friedman and Schwartz's argument assumes that the bank failures had a much stronger effect on the demand for deposits than on the demand for money. For a first approximation, the latter may be ignored.

[6] In Friedman and Schwartz's story, income would not have declined nearly as much as it did in the absence of the banking panics. In this alternative story, income would not have been much higher in the absence of the panics.

ans is of more than passing interest. Our inability to settle on a single story of the Great Depression, or even to devise powerful tests of alternative stories, suggests that a certain diffidence with respect to current policy prescriptions is in order. It also makes it hard to generalize from the experience of the 1930's because it is not clear which aspects of that time were critical in the economic decline. Nevertheless, a stab at comparison is worth making. Is there anything in current macroeconomic data that suggests that we are in for a period of substantial and sustained underutilization of economic resources on a scale approaching the experience of the 1930's?

Despite current optimism on this score, there are a number of similarities between the recent decline and the beginning of the Great Depression. Some of them are shown in Table 1, where annual data is used in preference to quarterly data to make the recent observations consistent with the available annual data from the 1930's. Annual rates of change of several macroeconomic variables are shown for the first two years of the Great Depression, for last year, and this year. The data for 1975 have been estimated from data on the first three quarters, but they should be accurate to the degree needed for this discussion.

The *GNP* deflator is listed in the first row of Table 1 because recent price history is so different from the price history of the late 1920's and early 1930's. It seems absurd to discuss, say, the nominal quantity of money without paying attention to the rate of inflation, but there are also objections (as we shall see shortly) to dealing solely with real balances. I therefore have shown the changes in a price index separately to emphasize the price movements removed in the calculation of real magnitudes.

The second and third rows of Table 1 show the growth rate of the real stock of money under two definitions. In nominal terms, the path of the money stock in the last two years was completely different than in 1929–31. In real terms, however, there is more similarity. The real money stock remained more or less constant in 1929–30 and rose in 1930–31; it fell slightly in 1973–74 and 1974–75. In neither period did the real money stock behave in an expansionary manner, and it fell more in the last two years than it did in the early 1930's.

TABLE 1—PERCENTAGE CHANGES IN SOME MACROECONOMIC VARIABLES, 1929,31 AND 1973,75 (Percent)

| | 1929–30 | 1930–31 | 1973–74 | 1974–75 |
|---|---|---|---|---|
| *GNP* deflator | −3 | −9 | +10 | +9 |
| Real $M^1$ | −1 | +3 | −4 | −4 |
| Real $M^2$ | +1 | +3 | −1 | −1 |
| Real stock prices | −16 | −26 | −36 | −7 |
| Real residential construction, 1958 prices | −39 | −19 | −27 | −22 |
| Real consumption expenditures, 1958 prices | −7 | −4 | −2 | +1 |
| Real *GNP*, 1958 prices | −10 | −8 | −2 | −3 |

*Sources:* Council of Economic Advisors, *Annual Reports*, 1975, 1971; Board of Governors of the Federal Reserve System, *Banking and Monetary Statistics* (Washington, 1943); Standard and Poor, *Trade and Securities Statistics*, 1974 and 1975; and *Survey of Current Business*, recent issues. $M^1$, $M^2$, and stock prices were deflated by the *GNP* deflator. The last column shows estimates made informally from data on the first three quarters of 1975.

What should we conclude from this comparison? If we believe that the demand for money is a stable function around which there is very little variation, that the interest-elasticity of the demand for money is low, and that the direction of causation runs from the stock of money to the arguments on the right-

hand side of the familiar equation, we must look for a fall in real *GNP*.[7]

This approach ignores interest rates and other financial markets; only an extreme monetarist would stop here. One financial market whose movements have been cited repeatedly as a cause of the Great Depression is the stock exchange. As can be seen in Table 1, prices on the New York Stock Exchange declined more from 1973 to 1974 than they did from 1929 to 1930, and the difference is quite large in real terms. And even though stock prices fell less in real terms this year than in 1931, the fall over a two-year period was almost exactly the same for 1929–31 and 1973–75. If the stock-market crash was a powerful deflationary force in 1930, there would seem to be cause for alarm now from this quarter also.

Turning to nonfinancial markets, the decline in housing in the 1930's often is cited as a primary cause of the Great Depression. And, as everyone knows, the construction industry is a serious casualty of the current financial picture. As Table 1 shows, the proportional decline in the real value of housing investment was only slightly smaller in 1973–74 than in 1929–30 and slightly larger in 1974–75 than in 1930–31. The data in Table 1 are only the tip of the iceberg; the history of construction is too complex to be summarized this simply. But a more detailed history would not refute the assertion that *if* a prosperous construction industry is needed for the health of the economy, as most Keynesian descriptions of the Depression seem to assume, then the recent decline in housing is extremely serious.

[7] This argument typically is made in nominal terms by monetarists, and the inflation rate is then subtracted from the growth of nominal income to get the growth rate of real income. If the income elasticity of the demand for money is one, that is, if velocity is constant as is often assumed, the two procedures are the same.

(See Ben Bolch and John Pilgrim.)

So much for similarities. There are also several striking discrepancies between the recent record and the experience of the 1930's differences that we hope are enough to justify the current optimism. The instability of foreign exchange markets, the difficulties attendant upon large shifts in international lending, and the problems of countries experiencing sharp changes in the terms of trade, all figure prominently in many stories of the 1930's. All of these problems are present today, but the structure in which they are taking place does not seem as vulnerable as the inter-war one. In particular, the era of floating exchange rates does not seem to be as vulnerable as the gold-exchange standard was.

In addition, the fall in real consumption expenditures was far smaller in 1973–74 than in 1929–30. The dramatic decline in consumer spending in 1930 was an important—possibly even critical—part of the story of the Great Depression. In my view, an autonomous fall in consumer spending in 1930 was a major factor blocking the recovery that contemporary observers expected until quite late in that year (see Temin 1976, Chapter III). If this view is accepted, then the current relative steadiness of consumption expenditures is quite encouraging.

This raises an obvious question: Why didn't consumer spending fall as much relative to the predictions of a standard set of expenditure functions last year as it did in 1930? A tentative answer is suggested by some recent work of Frederic Mishkin (1975a and b). Consumer expenditures, Mishkin argues, are related to the balance-sheet position of households, in which the stock of money figures only marginally. It has by now become a commonplace that household spending plans are in part a function of the household's net wealth. In addition, Mishkin argues

that the costs of selling illiquid assets—or in the extreme case of going bankrupt—induce household spending to be a function of the household's leverage as well. At the same level of net wealth, consumption expenditures will be inversely related to the volume of debt.

People were increasing their indebtedness throughout the 1920's and they borrowed heavily in 1929. When the stock-market crash came, the net wealth of households was reduced and their leverage was *increased*. (The decline in the value of their assets both reduced their net wealth and raised the ratio of their debts to their assets.) The combination of these two movements caused consumption expenditures to slump dramatically in 1930.

This effect was not present to the same degree in 1974 for two reasons. There was no accumulation of debt in 1973 comparable to the build-up in 1929. And the inflation of 1974 reduced the real value of debt while the deflation of 1930 increased it. Consequently, while the effect of the decrease in consumer liquidity was apparent in 1974, it did not have the dramatic macroeconomic implications that it did in 1930.

Finally (in our list of optimistic factors), there does not seem to be a substantial risk of repeating the sequence of bank failures that characterized the early 1930's. The *FDIC* was able to contain the failures of the United States National Bank of San Diego in 1973 and the Franklin National Bank of New York in 1974 in ways that aborted any rise in destabilizing speculation against banks. There does remain—at the time of writing—the risk that a default by New York City might weaken banks holding the city's paper and lead to a banking panic, but this risk appears small. The Federal government probably will not let the city default, and investors probably will be happy with a negotiated write-down of assets in place of a court-directed write-down. Even if the city does default, this possibility has been extensively discounted. An event so fully anticipated should not initiate a panic, although it may have less dramatic contractionary effects by raising the interest rates at which many potential purchasers of real capital can borrow.

Our view of the Great Depression is hardly complete. In a serious discipline, it must be a cause of concern that one of the major events in our economic history is still so poorly understood. Nevertheless, our knowledge of the Great Depression is still sufficient to give us some assurance that the current position is not nearly as serious as the economic condition in 1930. It would be nice to say that this was the result of more enlightened macroeconomic policies by our current leaders, but the story just sketched does not support such a conclusion. We are the beneficiaries of some changes in the structure of the economy and luck rather than the fruits of expert leadership.

# The Demand for Money from the Great Depression to the Present

*By* ARTHUR E. GANDOLFI AND JAMES R. LOTHIAN*

Myths and legends about the Great Depression have dominated the public's perception of the business cycle. They have shaped government policy and, until recently, they have even held powerful sway among economists. In the immediate aftermath of the Great Depression, many economists came to question the fundamental concept of economic equilibrium. Velocity was thought to be highly unstable—as in the case of the "liquidity trap"—so that the quantity of money supplied was consistent with any level of nominal income. In the real sector, there was the frightening specter of underemployment equilibrium. Following a shock to the economy which reduced output and depressed prices, there were reputedly no forces at work that would achieve a return to full employment. What is remarkable about these ideas is that they gained such widespread acceptance in the economics profession despite the absence of any systematic supportive evidence.

As empirical evidence on the economy accumulated, more and more economists turned away from such views. Milton Friedman and Anna Schwartz's explanation of the monetary nature of the Great Depression provided the major stimulus for this reevaluation. Their conclusions were buttressed by the results of other statistical studies which have dealt directly with the 1930's, such as those by Martin Bronfenbrenner and Thomas Mayer, by Allan Meltzer, by Clark Warburton and most recently by Arthur Gandolfi. Their arguments have been given support by the numerous studies of money demand that have demonstrated its essential stability under diverse institutional and economic conditions.

The current recession has led to a renewed concern over economic instability. This concern is evidenced by the resurrection of a whole list of proposals reminiscent of the 1930's—running the gamut from *WPA*-type employment projects to national economic planning. The Great Depression again is pointed to as the premier example of economic instability; the current recession as its second coming. One reason for the persistence of the controversy surrounding the Great Depression lies in the difficulty in testing competing explanations of the behavior of the economy during short historical episodes. The number of truly independent time-series observations is very limited and the degree of collinearity among possible explanatory variables is too high.

Our paper focuses on one of the controversies noted above—the behavior of the demand for money during business contractions. This issue is of particular importance since a stable demand function for money is an essential requirement for a monetary explanation of the cycle. To get around data limitations, which result from the use of time series alone, we use yearly cross-state data for the period 1929 through 1968. This approach increases

* First National City Bank. We are grateful to John Maher for his extremely competent assistance in the preparation and analysis of the data. We also want to thank Thomas K. Barneby, Phillip Cagan, Stanley Diller and Anna J. Schwartz for their comments on an earlier draft and Deborah Wenninger for her programming assistance.

our degrees of freedom and reduces problems of collinearity. It also provides the possibility of reconciling the pre- and post-World War II movements of velocity which have made it difficult to say anything definitive about velocity and the demand for money over short time periods like the early 1930's.[1]

## I. The Model and the Data

As a model of the demand for money we assume a fairly standard relationship of the form:

$$ln\,(M/PN) = \beta_0 + \beta_1\, ln\, y_p + \beta_2\, ln\,[(1 + RB)/(1 + RM)],$$

where $(M/PN)$ is per capita real total commercial bank deposits, $y_p$ is permanent per capita real personal income and where the bracketed term is the ratio of the value in the next period of a dollar invested in long-term bonds to the value in the next period of a dollar held as deposits—a measure of the opportunity cost of holding money.

The data we use cover the continental United States and the District of Columbia for the forty years from 1929 through 1968. Real per capita money holdings are estimated by deflating total commercial bank deposits for each state by the national consumer price index and by total state population. In calculating the state permanent income series, we used an exponentially declining weighted average of state per capita personal income with an initial weight of .33 and an allowance for separate state trends in income. The rate of interest paid on deposits was calculated by dividing the total interest paid on deposits, net of services charges on demand deposits, by a weighted average of June and adjacent December deposit figures.

## II. Empirical Results

We obtained estimates of the parameters of our money demand function from a wide variety of regressions—individual yearly cross-state regressions and pooled regressions, for the full 40-year period and for different subperiods.[2] We find that on the whole the demand for money has been stable over these 40 years. The standard errors of our regressions show little variation whether we go from period to period or whether we aggregate temporally. And the income and interest rate coefficients obtained from regressions run over the five-year and ten-year subperiods are remarkably stable. These regressions are presented in Table 1.

The income coefficients from the five-year regressions range from 1.20 to 1.42 and, for the 10-year regressions, from only 1.29 to 1.35.[3] Interest rate coefficients indicate an inelastic response of money demand to interest rates in all instances. In the five-year regressions, however, the effect of interest rates on the demand for money is considerably less stable than that of income. The coefficients themselves go from –4.74 to –15.70; the elasticities (estimated at the mean) from –.13 to –.53. But in the 10-year regressions this

[1] Prior to the war, velocity in the United States—particularly that of $M^2$—trended downward, suggesting to many observers a secular decline. In contrast, the velocity of $M^1$ increased more or less steadily since 1946, while the velocity of $M^2$ increased from 1946 until the early 1960's, remaining relatively constant thereafter. Not surprisingly, the bulk of the income elasticities estimated in demand for money studies with postwar data have been markedly lower (.5 to .7) than the longer term estimates (1.0 to considerably above) covering both the prewar and postwar periods.

[2] All regressions which include the years 1929 through 1936 contain current and lagged failure rate variables. For justification of the variables see Gandolfi's earlier paper.

[3] Our finding that the income elasticities estimated cross-sectionally are both stable and greater than unity casts considerable doubt on the hypothesis that the postwar rise has been caused by a decrease in the income elasticity of demand. It implies that the low estimates of income elasticities others have found using postwar data are the results of specification bias rather than any systematic alteration in income elasticity.

[a] For 1929–55 bank deposits (as of June 30) came from *All Bank Statistics* and for 1956–68 from the E.4 call reports, both of the Board of Governors of the Federal Reserve System. For 1929–48 interest expenses of banks came from the *Annual Reports* of the Comptroller of the Currency and for 1949–68 from the *Annual Reports* of the Federal Deposit Insurance Corporation. Long-term bond rates came from Standard and Poors, *Trade and Security Statistics;* state population from the *Population Report* of the Bureau of the Census; and both state personal income and the consumer price index from the *Survey of Current Business* of the Bureau of Economic Analysis.

The $\bar{R}^2$ omits the contribution of the yearly intercepts in the last three regressions. The elasticity of the interest rate variable, calculated at the mean, is $\epsilon_r$ and the numbers in parentheses are absolute values of $t$ statistics.

variation decreases markedly, with the coefficients ranging from –11.10 to –12.68 and the elasticities from –.28 to –.42. What the pattern of the interest rate coefficients shows is that the exact opposite of the liquidity trap, reputed to have characterized the 1930's, occurred. Interest elasticities fell as the level of interest rates declined.

To analyze further the stability of our estimates we ran separate yearly cross-state regressions for each of the 40 years. In these regressions, both the income and interest rate coefficients varied more widely than in the five-year pooled regressions. Income coefficients ranged from 1.06 in both 1966 and 1967 to 1.50 in both 1950 and 1951, rising fairly consistently from 1.28 in 1929 to the peak of 1.50 and thereafter declining until they reached low points in 1966–67. The interest rate coefficients were even more widely dispersed than the income, ranging from –30.93 in 1967 to 16.98 in 1946.[4]

[4] We suspect, however, that these estimates overstate the true variability in interest rate coefficients. Since the long-term bond rates are the same for all states, variations in our interest rate variable in any one year will be due totally to differences in the rate of interest paid on money in different states. For years in which these differences are small—such as from the mid-1930's to the early 1950's—it will be difficult to obtain good estimates. Accordingly, the pooled regressions may give a more accurate picture, than the yearly regressions, of the effects of interest rates on money holdings.

The differences over time in our yearly estimates of demand functions are reflected further in results of analyses of covariance. For the period as a whole, and for the subperiods 1929–48 and 1949–68, we rejected the hypothesis of homogeneity of the yearly regressions. The $F$ ratios to test the significance of the temporal differences in both slopes and intercepts were 2.27 and 1.54 for the subperiods and 3.02 for the whole period. None of these is of overwhelming magnitude, but they are all statistically significant at the .01 level.

What we want to find out is the source of this apparent instability. We wish to discover first whether it is due to a change over time in the relationship between money holdings and the explanatory variables—a change in the income and interest rate coefficients—or to some purely time-related omitted variable which would show up as a change in the intercepts. More important for the purposes of this paper, we want to know whether the apparent instability is essentially a cyclical or a secular phenomenon.

In answer to the first of these questions we found that we could account for the instability in yearly regressions by changes in intercepts rather than changes in the income and interest rate coefficients. For both of the 20-year subperiods and, more importantly, for the period as a whole the differences in yearly slope coefficients became highly insignificant after we allowed for separate yearly intercepts. The $F$ ratio never exceeded .88 in any of these three instances. We also ran a covariance analysis of the differences between the coefficients of interest rates and income in the 1929–48 period versus the 1949–68 period, after allowing for differences in yearly intercepts within each subgroup. The regressions themselves are presented in the bottom half of Table 1. The visual impression of stability is further confirmed by the statistical tests. The differences in slope coefficients between these two subgroups are insignificant at the .05 level—an $F$ ratio of 1.11.

Covariance analyses performed for the 1930's alone indicated homogeneity of slope coefficients for that decade. For the separate five-year periods 1929–33 and 1934–38 and for the two combined, the yearly income and interest rate coefficients showed no significant differences after we allowed for separate yearly intercepts. When we considered slopes and intercepts together we could not reject the hypothesis of homogeneity for the yearly regressions within the subperiod 1934-38 but could reject it—just barely at the .05 level—for the years within the subperiod 1929–33 and within the whole period 1929–38.[5]

To investigate the source of the instability of yearly intercepts we ran several tests. One was based upon regressions with separate intercepts for reference cycles, measured peak to peak. Comparing these regressions with regressions with single intercepts showed that the cyclical intercepts significantly reduced the unexplained variance for both the whole period and for the two 20-year subperiods analyzed separately. Comparing the regressions with cyclical intercepts with the regressions with separate yearly intercepts showed that the variation within cycles remained significant. However, as Table 2 demonstrates, the greater portion of the variations left unexplained by income and interest rates was among cycles and not within. Judged in terms of the mean square due to regression on the dummy variables for cycles relative to the mean

[5] This instability of the intercepts for the first five-year period differs from the results presented by Gandolfi in an earlier article. The difference is due to differences in the treatment of the two purely temporal variables—the interest rate and the price index. Gandolfi's deflator was implicitly permanent rather than the current prices used here. His interest rate variable was $ln\ (1+RM)$, which allows the effects of changes in the numerator of our expression to be picked up by the intercept.

square due to regression on the dummy variables for years (within cycles), it was almost eight times as great for the full period (1.039 versus .136). Judged in terms of the decrease in residual variances it was twice as great (.004 versus .002). Our conclusion is that the instability that we have uncovered is much more a secular than a cyclical phenomenon.

This conclusion is given further credence by an additional test. When we included a dummy variable for the contraction stage of all reference cycles in the regressions with individual cyclical intercepts, in no instance—in neither the full period nor the two 20-year subperiods—

TABLE 2—COMPARISONS OF INTER AND INTRA CYCLICAL VARIATIONS IN THE DEMAND FOR MONEY[a]

| | Residual Variance from Regression With | | | Variations Due to Differences[b] | |
|---|---|---|---|---|---|
| Period | Single Intercept | Cyclical Intercepts | Yearly Intercepts | Among Cycles | Within Cycles |
| 1929–68 | .045 | .041 | .039 | 1.039 | .136 |
| 1929–48 | .045 | .043 | .041 | .662 | .176 |
| 1949–68 | .039 | .038 | .038 | .135 | .082 |

[a] Data sources are given in Table 1.

[b] The variance among cycles is the difference in the sums of squared errors from regressions with single and with cyclical intercepts and the variation within cycles is the difference in the sums of squared errors from regressions with cyclical and with yearly intercepts, both divided by the appropriate degrees of freedom.

was this variable anywhere near significant. Moreover, its coefficient, which measures the deviation in contractions relative to expansions, was never greater than 1.6 percent. This evidence shows that even though there are significant variations in money demand within reference cycles they are not attributable to the cycle per se. They may merely be an extension of the departures we have observed among cycles.

## III. Summary and Conclusions

The stability of the demand for money function is an issue that economists cannot ignore. As long as there exists a stable demand for money function, movements in the supply of money are the crucial determinant of movements in nominal income and prices. Our results, based upon time series of cross-state data, show that money demand has been basically stable both over the whole period we have investigated and in individual years of the decade of the 1930's. And the instability that we did uncover in our estimated demand functions is predominantly secular rather than cyclical. So our results imply that cyclical declines in general—and the Great Depression in particular—neither stem from, nor are aggravated by major structural changes in the demand for money.

Our findings also confirm the efficacy of monetary policy in counteracting substantial cyclical declines. They strongly suggest that, regardless of the initial cause of such a downturn in aggregate demand, changes in money supply can be a useful palliative. The argument by Friedman and Schwartz that the Federal Reserve could have mitigated the severity of the Great Depression seems to us, on the basis of our analysis, to be correct. This does not mean, however, that our evidence justifies continual "fine-tuning." We observe statistically significant short-run departures from our model. Such errors may make countercyclical policy of limited use in anything other than periods of severe economic problems.

Inherent in the Friedman and Schwartz position is the proposition that had the supply of money not been drastically shrunken between 1929 and 1933, the fall in income would have been self-limiting and relatively mild. The alternative explanation, that this decrease in the supply of money was a consequence rather than a

cause of the substantial fall in economic activity, is a logical possibility, but one which we find totally unconvincing. It implies that a fall in the demand for money due, say, to a fall in income will bring about a fall in the supply. There is no obvious reason why this would be the case. To argue so, one would have to demonstrate that the proximate determinants of the supply of money—particularly the deposit-currency and deposit-reserve ratios—are sensitive to the factors influencing the demand. But this argument is inconsistent with the evidence. If demand and supply were interdependent, then in view of substantial differences in conditions of supply over our sample period we would expect to see a good deal of temporal instability in our estimated income and interest rate coefficients. But since that was not the case, we suspect that the degree of interdependence has been small. The evidence accumulated by Phillip Cagan in his analysis of the money supply process leads to the same conclusion. Cagan found that the major movements in the deposit-currency and deposit-reserve ratios during severe reference cycle contractions were the result of panics rather than the falls in economic activity. He concluded further that these panics were themselves episodic and not the products of income declines.

If the influence in the Great Depression ran from income to money rather than the other way around, then it was indeed an historical anomaly marked by fundamental one-time changes in the way the general public and the banking sector formed their preferences. And since we find no evidence of such changes in the overall demand for money we are exceedingly suspicious of the argument that they occurred in these other areas of the economy.[6]

[6] Michael Darby's paper further substantiates this conclusion. He shows that the real sector of the economy had a much greater tendency to move toward full employment in the 1930's than was previously believed.

# War-Related Debts and the Great Depression

*By* HEYWOOD FLEISIG*

At the conclusion of World War I, war-related debts were about $12 billion, an amount greater than total *U.S.* private long-term foreign assets, and equivalent to perhaps 15% of *U.S.* national income. Every major western country owed something to someone, but on net most of the war debts were owed to the United States by France, Great Britain and Italy; these four countries in turn, were to receive most of the payments by Germany on the reparations account. The largest single net creditor was the United States, the largest single net debtor was Germany.

The heated and lengthy economic debate about war-related debts, conducted in the context of passionate moral and political disputes, produced two distinct strains of thought: one was the well-known discussion of transfer; the other, less adequately incorporated into the literature, held that the war-related debts critically disrupted the international financial system, possibly started the depression, and probably aggravated it.

No simple, direct line can be drawn, however, from war-related debts to world economic activity: payments on war-related debt were made in the 1920's with no obvious adverse effect on economic activity; payments were cancelled in the 1930's with no obvious beneficial effect on economic activity. Accordingly, most accounts of the world depression center on elements other than war-related debts.

Therefore, this paper begins by raising some analytical issues about the relation between the war-related debts and income, before turning to the role of war-related debts in an explanation of the depression. It then argues that these debts had no important role in starting the world depression, some role in aggravating it, and a central role in the German depression. Although war-related debts did not begin the world depression, the analysis used to reach that conclusion indicates that then-contemporary concern about the economic effects of the debts was probably warranted, that even without a world depression eventual German default was likely, and that such a default probably would have created at least a mild world recession. The paper concludes with a discussion of some implications for the international economy today.

## I. International Debt in the International Economy: Some Conceptual Considerations

First, let us consider the notion of the "ability" to repay a foreign debt. Given the Marshall-Lerner conditions, depreciation by the debtor country will increase its trade balance measured in dollars or gold, the units of account that nominally valued the debts. The debtor cannot, however, increase its trade balance indefinitely. Given a full employment output dependent on techniques and factor quantities, and assuming that physical capital cannot be transferred to satisfy the debt,

* Division of International Finance, Federal Reserve Board, and University of Maryland. I am indebted to Ralph Bryant, Michael Dooley, Edwin Truman, Lance Girton, Dale Henderson, Peter Isard, Anna Schwartz, Jeffrey Shafer, and Mack Walker for several helpful comments and suggestions. The views expressed herein are solely those of the author and do not necessarily represent the views of the Federal Reserve System.

increases in the trade surplus can occur only at the expense of domestic consumption and investment. Minimum acceptable consumption and investment determine the maximum trade surplus and, thereby, the maximum rate at which the debt can be reduced. The debtor's maximum trade surplus will be lower if the creditor takes measures to reduce his counterpart trade deficit, but the maximum will exist even where the creditor does not take such measures.

The maximum rate of repayment need not be the optimum rate of repayment. The optimum rate of repayment is a variant of the now-familiar question of the optimal social savings rate. While the debt-repayment problem has its own interesting features, such as the relation between the terms of trade and the rate of repayment and the imposition of a fixed minimum total social savings equal to the debt imposed, all that need concern us here is that when the optimum rate is less than the scheduled rate, the debtor will optimally roll over the debt with private or public international borrowing.

It is helpful, then, to distinguish three rates of repayment: the maximum rate, the optimum rate, and the rate actually scheduled in the debt. A debtor may be "able to pay" a debt in the sense that the present value of the maximum trade surplus exceeds the present value of the debt. The debtor, nonetheless, must roll over part of the debt if an annual scheduled payment exceeds the maximum annual payment; it will choose to roll over the debt when the annual scheduled payment exceeds the optimum annual payment. The rolling over of war-related debts onto private account, and the accompanying increase in the net U.S. creditor position toward the debtor countries, need represent neither inability nor unwillingness to pay by the debtors, though it was often so criticized during the interwar years.

The roll-over of the original debt can increase the probability of default, particularly if the rolled-over debt is of shorter maturity than the original debt. Consider first a world with only war-related debt whose repayment schedule is fixed and known with certainty. If maximum attainable income and minimum consumption and investment are known with certainty, then the maximum surplus is known with certainty, and default is either certain or impossible. Default is certain if the present value of the debt exceeds the present value of the maximum surplus or, in the absence of private lending, if the maximum surplus in any year falls short of the scheduled payment; otherwise, default is impossible. A probability of default emerges only when these elements have stochastic components; while the repayment schedule may be known with certainty, there will be random components in both income (e.g., crop failures, the effects of foreign recessions, errors in domestic economic policy) and in consumption (e.g., a cold winter).

This probability of default will change when we introduce a private international capital market in which the original public debt can be rolled over. Where default was originally due to an annual scheduled payment greater than an annual maximum surplus, but where the present value of the maximum surplus exceeds the present value of the debt, the private market makes payment possible. However, should maturities shorten as debt is rolled over, the new debt may rise so that the fraction due in any year exceeds the maximum ability to pay. Then the probability of default will also depend on the chance that creditors will recall such a fraction of rolled-over debt in a year or that this debt cannot itself be rolled over. In this way, the probability of default will also depend on stochastic elements in the international loan market.

Whether default mattered in the world depression depends on its consequences as well as its probability. Default in the 1930's had several contractionary effects. First, default was typically preceded by a period during which default was not certain, when the debtor pursued contractionary policies to avoid default. Private debtors reduced consumption and investment; public debtors increased interest rates and taxes and reduced government expenditures. Second, the prospect of default reduced the availability of loans to the debtor, making the measures necessary to avert default more extreme. Third, once the default occurred, there was a period of uncertainty during which *ad hoc* institutional arrangements were made, coupled with stringent expenditure conditions placed on defaulters by lenders making new loans. Since the probability of default is not independent of the rate of interest charged on the loan and there are interest rates at which no rational lender will lend, the conditions we have described may not show up in the interest rate. We may regard the supply curve of loanable funds as backward-bending with respect to the interest rate and shifting with respect to the constituents of default discussed earlier.

In addition to the effects of debt-related flows, we must consider the effects of changes in the real values of the debts themselves on public and private expenditure decisions. Changes in prices and interest rates produced immense changes in the real values of war-related debts. There is only limited indication, though, that national economic policies were set with such international balance sheet considerations in mind: on such grounds some support was given to the appreciation of sterling in 1925 and some opposition offered to depreciation of the mark between 1930 and 1932. There is no evidence that countries that were creditors on war-related debt account expanded income because of increases in the real value of their assets, so we may regard the overall governmental response to increases in the real value of the debts as contractionary.

Private international debt was tied to war-related debt in several ways: private parties held most of the rolled-over public debt, debtor countries sometimes undertook domestic policies to increase the current trade surplus that reduced the ability to pay of private debtors within that country, and policies such as suspension of foreign payments affected the repayment of both private and war-related debts.

Changes in the price level are commonly taken as having no effect on aggregate expenditure through changes in private wealth by assuming equal marginal propensities to consume out of wealth for both debtor and creditor. But analogously treating a change in the probability of default as a change in the distribution of expected wealth would neglect an important asymmetry: while a private debtor will reasonably perceive that expenditure reduction lowers the probability of default, a private creditor will reasonably perceive no connection between his own expenditures and the debtor's default. We may also question whether debtor and creditor view the probability of default equally: massive repatriation by debtors of bonds in default suggests that debtors may have seen the probability of default as lower than did creditors, implying that the expected value of the debt fell more for the creditor than for the debtor.

## II. Explaining the World Depression

A request for an explanation is a request for a causal statement. Since causation is ultimately defined by a model, explaining an event is tantamount to subsuming it under the appropriate model. In building a model of the international economy that

incorporates the features of international debt we have discussed, two difficulties would arise: first, there is a lack of general agreement on what the nondebt features of this model would be; second, assessing the quantitative importance of war-related debts would require the application of estimated parameters to variables at the extremes of the sample range in a model that features some severe discontinuities.

Surmounting these difficulties, we would still find ourselves facing a number of apparently appropriate explanations; we should first agree on some usage concerning the notion of "explanation." Essentially our agreed-upon model would take one set of variables exogenous to the economic system and another set of policy variables and transform them into the endogenous variables whose behavior we seek to explain. The structure that performs this transformation, depending on the period of time for which the model is built, comprises some traits thought immutable, some that are endogenous but change with sufficient slowness to be taken as constant, and some traits that may be changed by government policy.

With such a model we could assess the relative importance of changes in exogenous variables, policy variables, and structure, where we would measure importance by the fraction of lost output for which each element accounts. In doing so we would distinguish explanations of the start of the depression from those treating the length and depth, but we could use this model to untangle those elements of the length and depth that are a longer-term endogenous response to the origin from those elements that revolve around later changes in exogenous variables, policy variables, or structure.

We also require a usage to deal with explanations phrased in terms of counterfactuals, such as "the depression was aggravated by the absence of proper fiscal policy." As a technical economic exercise, our model could readily answer the question of how much less severe the depression would have been had different fiscal policies been pursued. It could equally well tell us how much less severe the recession following the War of 1812 would have been had James Madison pursued countercyclical fiscal policies. But while each is an illuminating technical exercise, the latter is a silly historical question while the former is not. This distinction rests on a historical judgment about the feasibility of the policy action or structural change in question, a problem of induction not substantially more difficult than was the statistical verification of the model.

We lack this splendid model. But discussing it in its near ideal form gives us a rough standard for evaluating the partial and imperfect explanations we are able to posit now. We haven't time here to evaluate all the candidate explanations, eliminating some and buttressing others, so I will tell one plausible story and try to show its relation to the war-related debts.

## III. War-Related Debts and the World Depression

The world depression began with the decline in *U.S.* long-term international lending in 1928 and 1929 and was considerably aggravated by the decline in *U.S.* imports in 1930 and early 1931. Both the decline in lending and in imports were of domestic, not international, origin. War-related debts figured only peripherally during this period, through events in Germany; we will discuss these events separately. At its birth, the world depression was the creature of the United States.

The decline in net *U.S.* long-term international lending was the combined result of an inflow of foreign funds to purchase *U.S.* stocks and a decline in *U.S.* purchases of foreign bonds, in turn due to the *U.S.* stock market boom and accompanying

restrictive Federal Reserve policies. The decline in *U.S.* long-term lending led to mild recessions in Europe directly through increased interest rates and indirectly through reduced imports from Europe by third countries who also borrowed in the *U.S.* market; both in Europe and among third countries restrictive policy actions were also undertaken to maintain gold-convertibility in the face of declining *U.S.* lending.

The decline in *U.S.* imports in 1930 and 1931 followed directly from the decline in *U.S.* income. This decline in income is not well-explained. Two leading candidate explanations are the wealth effect of the stock market crash and a decline in residential building; these, in turn, require explanation, but it suffices for us to note that promising trails do not lead to foreign or international factors. The decline in *U.S.* imports led to reductions in incomes in Europe and among third countries through channels similar to those described for the drop in lending. The decline in aggregate demand was now sufficient, however, to sharply reduce the absolute and relative prices of primary commodities and to place in question the repayment of debt by primary producing countries and regions. Of particular interest to us are the agrarian regions of the United States, Germany and Austria.

Payments on war-related debts were small relative to these changes and it is unlikely that their absence would have significantly altered any market or policy response, except that of Germany, from 1928 to early 1931. From early 1931 to 1933 war-related debts cannot be so easily dismissed. It is possible that without the large short-term international debt amassed by German banks in the process of rolling over the war-related debts, the German banking system would have withstood the failure of the Austrian Kreditanstalt, itself largely a function of the fall in agricultural prices. If so, then the thread that runs from the German bank failures to the German suspension of payments and, thence, to the devaluation of sterling and the 1931 *U.S.* bank failures might have been broken earlier. But this is a list of "ifs" quite difficult to assess and it is terminated with a formidable counterfactual explanation based on the question: Why did the Federal Reserve system permit the bank failures?

## IV. War-Related Debts and the German Economy

While war-related debts may not be a major element in explaining the world depression, they are crucial in understanding German economic and political conditions in the 1920's and early 1930's. Whether the German inflation of 1923–24 followed from excessive international transfers that depressed the mark and raised domestic prices or, more plausibly, from government deficit financing of massive relief payments to Ruhr workers who were passively resisting the Franco-Belgian occupation, there is little question that the inflation centered on reparations. It has been suggested that this inflation destroyed the German middle class and paved the way for Hitler. This is an exaggerated story. Hitler attempted the Beer Hall Putsch at the peak of this inflation, attracted a small following, was promptly suppressed by the army, and remained a minor actor in German politics from 1924 to late 1928. Rather, Hitler's rise in power was highly correlated with the rise in German unemployment; his political support came from agrarian and middle class groups substantially damaged by the deflation of 1930 and 1931; his program repeatedly emphasized public works projects for the unemployed and emergency loans and price supports for farmers.

We earlier conjectured that without war-related debts, Germany might have

absorbed the collapse of the Kreditanstalt while pursuing less contractionary policies. It is more certain that war-related debts prevented a more active German response to the depression. The Brüning government faced difficult policy choices from 1929 to 1932. Increased government spending or reduced taxes would have reduced the current account surplus and increased the government deficit. That, in turn, might have indicated an "unwillingness to pay" that would have undermined the attempts by the German government to have reparations reduced on the grounds of the hardship their payment caused Germany. These attempts succeeded at the Lausanne Conference of 1932. An expansionary monetary policy would have had the same effect on the economy and probably on the views of creditors; under the Dawes Plan the Reichsbank had agreed to keep the discount rate above 5 percent. The only remaining route through these difficulties was the devaluation of the mark, a possibility apparently rejected partly because it would increase the burden of the debt measured in German goods but more because it would raise prices. Brüning pursued a brutally contractionary policy in 1930 and 1931.

Apparently perceiving the political dangers of these economic policies, Brüning shifted course in 1932 and began planning massive public works projects. These were delayed in part by the specific objections to them by foreign creditors of Germany and were not instituted until after Von Papen replaced Brüning. Substantial amounts of funds were spent only after Hitler became chancellor; it is, incidentally, such public works expenditures and not spending on armaments and mobilization that account for the bulk of German expansionary fiscal policy from 1932 to 1935.

We have all been taught that reparations had something to do with World War II, but it is useful for economists to recognize that the most plausible channel through which reparations operated was their impact on German unemployment policy. No German government paid reparations enthusiastically, but German voters repeatedly chose the course of the center parties in gradually reducing payments rather than endorsing the right-wing's persistent proposals of repudiation. It would be reckless to explain world history from 1933 to 1939 in terms of German unemployment from 1929 to 1932, but even a small contribution to those events deserves respect and attention.

## V. Summary and Implications for the International Economy Today

In explaining the world depression, we have linked the war-related debts to the absence of more expansionary German fiscal policies and to the chain of bank failures. However, were we to simulate our near ideal model, we would probably find that more expansive German policies would not have changed the world income path substantially, while the bank failure story, itself highly conjectural, loses much force against the historically plausible counterfactual explanation centering on the failure of the Federal Reserve to prevent the U.S. banks from collapsing. The war debts aggravated the depression by creating a structure that produced a larger decline in income from any given shock, but given the largely domestic origins of events in the United States, a world without war debts would still have had a large depression; world depressions, like many other things, do not succeed unless the United State cooperates. All this is consistent with the possibility that the total cost of the depression was so great that even a relatively small contribution might itself have a fearsome consequence.

What is the implication of this for today's economy? History is an uncontrolled experiment and deriving lessons from it through analogy is hazardous. It is better not to proceed by comparing and contrasting war-related debts and oil-related debts. Rather we should regard history as the full-dress acting out of our models, less precise than an econometric representation, but richer in suggesting how our models might be altered to better suit our needs. The analysis discussed earlier, based on the war-related debt episode, suggests that concern over those debts was warranted; that had the depression not intervened, the rolling over of the war-related debt would have made the German economy increasingly sensitive to autonomous disturbances of given size until default eventually occurred. Such a default, with its contractionary preface and aftermath, would probably not have led to anything like the world depression; but we cannot make this argument with great certainty and, moreover, all this is consistent with the absolute loss in output being quite large.

The implication for the oil-related debt is similar. It is a large debt and an optimal pattern of repayment will involve considerable rolling over. Until we have made operational these notions of the optimum incurring and repaying of international debt, it will be difficult to assess the performance of the private capital markets in dealing with the problem. Until these questions are worked out, it seems preferable for intergovernmental supplementary lending arrangements to err on the generous side. The role of the war debts in the world depression gives some notion of the global economic costs of mismanagement, while the role of war debts in the German depression should provide a flavor of the potential social and political consequences of excessively rapid real economic adjustment.

# THE FLEXIBILITY OF WAGES AND PRICES

## Inflation Theory and Policy

*By* William D. Nordhaus*

The short-run behavior of aggregate prices is one of the most significant and controversial of macroeconomic variables. In a much-criticized section of the *General Theory*, Keynes suggested that a capitalist economy in recession would show little price response to changes in aggregate demand. At the other extreme, some monetarists have argued that changes in aggregate demand lead rapidly to price changes. Phillips and his followers lie somewhere between these views, holding that some but not all of an increase in nominal demand ends up in higher prices. Where does this debate stand today? My reading is that, while far from the truth 40 years ago, the truth is coming closer to Keynes every year. The current state of the *U.S.* economy, and particularly the refusal of wage inflation to moderate significantly in recession, demonstrates how much inflation has been insulated from the pressure of demand.

Much theoretical writing has been devoted to explaining the inflationary process. A useful way to model a Western economy resembles a theory of a "dual-economy." One set of markets, call them *auction markets*, are the typical competitive supply and demand model, exhibiting flexible prices. Sometimes these are internationally traded goods or "exposed" goods as in the Scandinavian inflation model, but this is not essential. Agricultural markets are rather clearly in this mold as are many security and raw commodity markets. At the other pole lie the *administered markets*. These tend to be markets where either buyers or sellers have significant market power, and one significant use of that power has been to restrain price movements. The administered markets contain much of the manufacturing, utility, and government sectors, and the labor markets are progressively becoming administered.

How do different market structures transmit inflation? R. G. Lipsey's original interpretation of the Phillips curve was as a Walrasian adjustment mechanism in a competitive market—wages respond to the disequilibrium in the labor market. The irony is that this seems a better description of price dynamics in an auction market, like the wheat market, than in an administered market like the labor market. A more important criticism is that the Phillips-Lipsey model has not incorporated inflation in a satisfactory manner; the customary modification of the Phillips curve for inflation is to add an *equilibrium* inflationary correction to the disequilibrium response, but this is an inelegant appendage under the Lipsey interpretation. Why should the response to a given state of disequilibrium vary at different inflation rates? This is similar to arguing that the laws of motion of a pendulum differ depending on its average velocity through space. It seems to me that the original Phillips-Lipsey curve is a reasonable way of representing disequilibrium price dynamics only in auction markets. In auction markets inflationary expectations get built into equilibrium auction-good prices through the effect on supply and demand,

* Dept. of Economics, Yale University.

and built into the time-sequence of auction-good prices through interest rates, but inflationary expectations do not get built into the disequilibrium adjustment mechanism for auction goods.

For administered markets we have a great deal of empirical evidence in hand. One area where the evidence is good concerns price behavior in the administered industrial sector. Wynne Godley, Kenneth Coutts, and I have examined price behavior in all *U.K.* manufacturing as well as in seven disaggregated industries over the postwar period. The main hypothesis we examined is whether price behavior can be adequately described as "normal pricing"—that is, are prices set on the basis of costs normalized for the cycle. We found, rather surprisingly, that prices were almost completely determined by normal costs. More precisely, once costs have been converted to normal average costs (costs are read off a cost schedule at the normal value of output) there was at most a whisper of an effect of the *actual* level of demand and costs on actual prices. Just to give an empirical flavor to these observations, we concluded that the effect of the average *U.K.* business cycle on manufacturing prices (for a given structure of costs) would be less than .1% in absolute value. It is unclear whether these limited empirical results should be extrapolated to other administered markets. Otto Eckstein and David Wyss, as well as Robert J. Gordon, have found very similar price behavior for the manufacturing and nonfood sectors of the United States, although the United States appears to be more sensitive to demand than the United Kingdom.

Do firms price labor in the same way that they price goods? Up until the time of Keynes, wages over the business cycle were assumed to be determined by the classical relation between the marginal value product and the wage. Even though Keynes later admitted that cyclical movements in the real wage were anticlassical, he did not purge this last vestige of classical thought from the *General Theory;* indeed this anachronism is still embalmed in most modern macroeconomic textbooks. A close examination of the cyclical movement in wages reveals that they parallel prices in the trend toward normal pricing. In the modern terminology, Phillips curves are apparently becoming much flatter in the short run, and it is clear that in deep recessions the marginal impact of unemployment on wage inflation is very small. At the same time, recent econometric work seems to indicate that wages are more responsive to inflation than in earlier years.

An approach to understanding these phenomena might run as follows: administered wages generally follow the principles of normal pricing, so that cyclical fluctuations are largely removed. In bargaining situations, employers are prepared to settle for a wage which will keep their profit margins constant. Obviously, this acts as a much more powerful restraint on wages when an entire industry is not at the bargaining table. Employees keep their eyes both on competing groups and on their expected growth of real income. If wages are in line with historical wage differentials, and real incomes grow as expected, after the usual rites of brinkmanship and bravado, the settlement can be reached. (In pure administered wage situations, without bargaining, the determinants would be much the same except that competing wages might be more important.)

This simplified model can be solved for the resulting wage settlement as a function of the lagged wage settlements (as well as entropic elements such as the deviation of wage differentials from a normal pattern), the rate of change of value-added prices, and the rate of change in

exogenous prices (that is, the price of imports to the administered sector). Such a bargaining model would predict that an increase in value-added price inflation would eventually be completely passed through into higher wage inflation. If the increased value-added inflation were completely balanced, then such a solution leaves all real variables (except the real return on noninterest bearing money) unchanged. But an attempt to pass through exogenous price inflation, such as that on oil and food, would be vigorously resisted. George L. Perry's evidence suggests that value-added prices do get fully passed through into wages while only 15 percent of exogenous price inflation (such as that due to food and fuel prices) is passed through.

The administered wage model points to lagged wages and value-added prices as the major fuel for continued wage inflation, while the administered price model points to normal average costs as the main determinant of prices. To complete the system, we need to consider the prices in the auction system. The principles behind auction price determinations are basically the classical principles of competitive supply and demand. The clearest examples are those for raw commodities such as those on international exchanges (copper, zinc, raw fibers, foodstuffs). Recent work in this area points to the importance of international supply and demand factors—demand appears to be at least ten, perhaps fifty times more important in explaining short-run price movements in these auction markets than it is in the administered markets. Auction prices provide much of the noisiness in price behavior over the last four years with unexplained elements — dramatic shifts in patterns of hedge buying or even speculation—playing a large role in the 1972–75 inflation.

Putting all these elements together we get three basic elements in the aggregate price equation. First, we see demand entering weakly through three routes: through the markup in the administered market price equation, through unemployment in the wage equation, and from auction markets. The nature of the nonlinearities means that all three responses are likely to be very weak when the overall level of utilization is low, but demand inflation is significant in periods of very high utilization. The second major effect is the momentum effect of the current and past rates of wage and value-added inflation in the administered price sector. Recent work indicates that, random shocks aside, the momentum effects dominate price and wage movements over the short run; this implies both that using demand to affect inflation has a small initial effect and that its effects are spread over long periods. A recent study of Michael L. Wachter, for example, indicates that the mean lag of demand on prices operating through the labor market is in the order of three to five years. The third major determinant is exogenous movements in auction prices. These may be due to a world boom largely outside the control of the national authorities, to variations in weather or ocean currents, to stock building in nonmarket economies, or to speculative fever.

The model of inflation outlined here is hardly new; Gardner Ackley outlined a similar model 15 years ago. Such a model explains relatively well price movements over the last four years (as is shown by Gordon or by John B. Shoven and myself). Why then have economic forecasts been so far off the mark in recent years? There are basically four reasons for the very poor price forecasts. First, the auction sector has been largely ignored, for differential movements in auction goods prices were insignificant until recently. Second, there appear to have been struc-

tural shifts—Phillips curves estimated today look remarkably different from those estimated five years ago. Third, even with today's models, inflation cannot be predicted with great precision. The exogenous element in auction prices was very large over the last four years, and one recent attempt to predict commodity prices shows errors of up to 50 percent in 1973 and 1974. Finally, the normal timing of the price-wage system has been wrenched by a successive tightening and loosening of price and wage controls. Gordon estimates that the loosening of controls in 1974 led to an inflation rate three percent above what would otherwise have occurred.

While the exact details of price behavior may differ from that painted here, the broad vision seems to accord with much recent empirical work. Unfortunately, it is quite difficult to describe a theory which can underpin the reality—leading to the description of administered pricing as a phenomenon in search of a theory. After three decades, the major intellectual problem continues to be the fact that so little of the response to demand shifts comes through prices and wages. Although some economists continue to argue that price movements are underestimated because of errors of measurement (through price shading in recession and vice versa), there is little evidence that the errors are substantial. Indeed the aggregate transactions price index of George J. Stigler and James K. Kindahl shows *less* cyclical sensitivity than the corresponding official price index. Moreover, the pervasiveness of price stickiness across time and space casts doubt on behavioral explanations that rely on the weakness of forces of selection to drive out nonoptimizing behavior without showing why such nonoptimizing behavior arises in so many situations in the first place.

Early explanations of normal pricing (such as Paul M. Sweezy or the more elegant Edmund Phelps-Sidney Winter model) relied on the structure of competitive forces. In Phelps-Winter, for example, firms respond with quantity because customers will emigrate to other firms if they do not. This class of explanation fails to explain why prices respond so much more completely and rapidly to cyclical changes in costs than to cyclical changes in demand. A more recent rationale elaborated by Arthur M. Okun embeds wage and price behavior in a search theoretic framework. Price stability on the part of a firm is seen as part of a more general trend toward standardization of product; when I drive into a MacDonalds, I know not only the menu, quality, and speed of service, but also the prices. The "normal" pricing rule can be interpreted as a form of implicit long-term contract, where the consumer is willing to pay slightly more, averaged over the cycle, for such a standardized product because of the reduction in necessary search costs. Why is normal pricing the standardized product that so many firms sell? A normal pricing rule is an equitable-sounding and easily-understood rule. Such a rule might well be the solution to an optimization problem in which the variance of prices is minimized subject to an average profits constraint. The new view of sticky prices as a service is a revolutionary reversal of populist views of Gardiner C. Means and his followers. Unfortunately, the new view has not been tested (nor are refutable hypotheses clearly stated).

The "dual economy" view of inflation has important implications for macroeconomic theory and policy. Thus the empirical description of the inflation transmission process casts doubt on extreme neoclassical and monetarist views of inflation. One such contention is that inflation is everywhere a monetary phenomenon. Presumably, in plain English, this means

that the money supply exerts a direct influence on the evolution of prices. In analyzing this question, one must be extremely careful to separate out the reduced-form effect from the structural effect. In the model outlined in the present paper, and neglecting second-order effects, money affects the price level only through its effect on aggregate demand. Thus in the normal price model, money does not enter directly into the structural equation but enters only through factor prices, while in the auction market money enters only by affecting excess demand. On the other hand, in a reduced form equation, all modern models except the extreme Keynesian depression models have money as an important determinant of aggregate demand, which influences demand curves in the auction markets and unemployment in the Phillips curve. Thus money should be insignificant in a properly specified structural price equation, while in a reduced form price equation money should be a powerful variable.

The distinction between reduced form and structural equations helps explain much recent econometric work. Reduced form price equations with money have performed surprisingly well. Yet in structural equations, such as in the Nordhaus-Godley, there is no perceptible influence of reversible cyclical factors in price determination, and there is no room for money to exert a direct role in price determination in the administered price sector. Gordon has found that a bivariate reduced form price equation with money is highly significant with a very long lag (much longer than is consistent with popular monetarist writings), but that adding money to the structural equation shows very little independent influence of money outside of the influence on the structural variables.

A recent strand of neoclassical thinking, associated with the writings of Robert Lucas, Thomas J. Sargent, and Neil Wallace, questions the efficacy of short-run macroeconomic policy because of the view of price dynamics. If expectations are rational and if prices and wages are flexible, policy is unable to "fool" people into allowing a deviation of unemployment or demand from the equilibrium rates even in the short run. These theories allow only a "learning lag" between policy and complete price flexibility. (The learning lag represents the necessary time for producers or consumers to learn that the real variables such as unemployment or output have changed.) In light of the fact that many policies are announced in advance—so that learning lags must be brief—and that the lags of output and prices in response to policy are so long, it is hard to understand how these theories could be seen as more than intellectual exercises. Put differently, is it plausible that the fall in capacity utilization over the current recession is either a fall in the "natural rate of utilization" or that it is unknown to the producers who actually leave the capacity idle?

A third major implication of the dual economy model is for international trade. Some recent work has stressed the importance of internationally determined prices in the transmission of inflation over national borders. According to the "law of one price," with fixed exchange rates, the world price level determines the price level in individual countries directly. This mechanism explains the puzzle as to the simultaneous outbreak of inflation in so many countries. Some monetarists have even pushed this to an extreme by arguing that price flexibility in individual countries will be a perfect substitute for floating exchange rates.

In terms of the dual economy model, these views seem to argue that the auction market is the dominant sector, and further that prices in the auction market are

set in world markets. Although no careful study of this proposition has been made, it seems clear that the significance of the "law of one price" is overemphasized. Clearly labor does not have one price, and outside of true auction markets there appears to be sufficient product differentiation and transport and tariff costs so that world prices exert but little influence on domestic prices in the short run. Godley, Coutts, and I have examined seven manufacturing industries in the United Kingdom to see whether the world price exerted any effect as against the normal pricing rule. We found on average the effect of the price of competing imports in the same industry was about one-tenth as strong as would be predicted by the law of one price. Similarly, Gordon found no room for competing export or import prices in his study of aggregate price behavior in the United States. I believe that these results cast suspicion on recent theories which rely on rapid adjustment of prices to either world prices or to demand.

The dilemma for policymakers in choosing between inflation and output is not only cruel but becoming crueler. Indeed, the inability to control both inflation and unemployment within acceptable institutions is the major flaw of Western economies today. The aversion to inflation has led Western countries into a recession of huge proportions, yet the inflation has hardly abated. Given the long lags in response, one must marvel at the steely nerves of politicians who sacrifice 10 percent of output today for a point or two in the inflation rate spread over the next five years. But in the long haul, there is a tension in a system where democratically-elected policymakers must choose between today's output and employment and next year's inflation. This kind of choice has led to political business cycles in the past and is embodied in the 1975 *U.S.* energy bill where politicians would only bite the bullet of price decontrol as long as the price explosion would come after November 1976.

Given the increasingly cruel dilemma and the unsatisfactory response of policymakers to the dilemma, it is tempting to search for new ways of controlling inflation. The ideal form of inflation control is one which reduces all nominally denominated values by the same percent without changing any relative prices or real magnitudes. The Achilles heel of past price-wage policies (except the relatively innocuous guideposts) has been that they confused inflation policy with income redistribution. By concentrating on individual sectors, they have attempted to change relative prices and aroused the fierce resentment of individual groups. Whether the 1962 steel controversy was justified or not, it can hardly be seen as distributionally neutral. The current contractionary route to deflation has even graver distributional consequences.

There is probably no such ideal anti-inflation policy, but economists have shown little inventiveness in designing durable antidotes to inflation other than recessions. One serious suggestion is an inflation tax which would penalize firms or workers to the extent that they deviated from a national norm. Such a mechanism would allow the decentralized decisions of which economists (and some politicians) are so fond. It would allow adjustment of relative prices, and when inflation rate is at the norm it would leave relative prices unchanged. Most important, such a measure would directly affect the bad—inflation—rather than first pummeling goods like output and employment.

# Some Problems in Wage Stabilization

By MICHAEL L. WACHTER*

A major issue in inflation theory and in the related empirical policy questions is the ability of the government to control wage inflation, in the short or the long run, through fiscal and monetary policy. This paper discusses issues involved in this question and offers some tentative conclusions. The problem areas can be divided into three headings: the difficulties in measuring a noninflationary rate of unemployment, the sources of wage rigidity in the labor market, and the impact of cost-push wage inflation.

## I. The Noninflationary Unemployment Rate

Attempts to stabilize the wage inflation rate depend on the ability to measure either the tradeoff between wages and unemployment, i.e., the Phillips relationship or to identify the unemployment rate (or rate band) beyond which the inflation rate tends to accelerate. Until recently most of the empirical literature focused almost exclusively on estimating the short-run Phillips curve.This functional relationship, however, proved itself an unstable tool for stabilization policy. The most widely accepted explanation for this instability is found in the various accelerationist models of inflation. In these models attention in stabilization policy is focused on the noninflationary rate of unemployment.

The natural rate or full employment rate, as originally discussed by Milton Friedman, referred to the long-run, "market clearing" unemployment rate in the labor market. At this rate, the actual rate of wage inflation is equal to the expected rate of wage inflation, and the economy has a tendency to gravitate towards this level of unemployment if left to its own devices. In addition, the natural rate might be expected to change only slowly over time. If the natural rate is known, stabilization policy can be utilized to speed a recovery when shocks in the private sector force a divergence from full employment.

An important development since the appearance of the natural rate literature is the notion that the unemployment rate at which inflation appears to be unchanging is not or at least has not been stable over the recent past and is not known with any degree of confidence. Specifically, the noninflationary unemployment rate ($U_{NI}$) is a short-run phenomenon incorporating an array of labor market forces. Some of the arguments of the $U_{NI}$ function, such as secular changes in relative wages or prices, are compatible with the natural rate concept of Friedman; other factors, are essentially nonmarket clearing, disequilibrium events. Incorporating this broad array of factors, it is not surprising that $U_{NI}$ is very difficult to calculate. In this section I discuss a few of the potentially large number of arguments of $U_{NI}$.

The evidence suggests that several independent and related forces have been operating since the early 1960's to push up $U_{NI}$ quite sharply. Of particular importance is the demographic shift towards younger workers and female workers. (See George Perry.) This is a reflection of the baby boom generation reaching the labor

* Associate professor of economics, University of Pennsylvania. This research was supported by the National Science Foundation and the National Institute for Health. The author wishes to thank Arthur Okun, Thomas Sargent, and Susan Wachter for many helpful comments.

market as well as the increase in the labor force participation rate of women and especially of younger women. Young workers, who naturally have relatively little specific human capital, have historically always had the lowest wages and the highest turnover rates. This shift in the labor force essentially suggests measuring workers in efficiency units.

A second force which may have been increasing $U_{NI}$ over the recent past is the rise, abstracting from cyclical swings, in the unemployment rates for the young and most female demographic groups. The basis for this position is that different skill groups are imperfect substitutes for each other so that a significant relative abundance of one group should cause an alteration in relative wage differentials. But if wage differentials among demographic groups are not sufficiently flexible, markets will not clear and unemployment rates will be forced to change as well (or in place of relative wages). In fact, the adjustment in a world where the skill requirements for capital equipment, etc., are largely fixed is likely to make it difficult for relative wages to clear the market. Further weakening the tendency of relative wages to change has been government policy measures. Dramatic changes in minimum wage coverage have prevented demand adjustments favoring lower skilled workers, and changes in unemployment compensation and welfare have steadily increased the *relative* reservation price of labor thereby lowering the cost of being unemployed. Studies of these policy measures, on balance, strongly support a displacement effect that would serve to increase $U_{NI}$.[1]

My attempts to date at creating a $U_{NI}$ series have concentrated on the demographic shifts described above and, to a lesser extent, the changing cost of unemployment. The estimated $U_{NI}$ series is shown in Figure 1. Given data and methodological problems, the series is a crude measure and, in particular, smoothes out much of the short-run variation in $U_{NI}$. The current estimated level of $U_{NI}$ in Figure 1 is 5.5 percent. Reasonably small changes in the method of constructing $U_{NI}$, however, can alter the estimated current level to as high as 6 percent.[2]

The above discussion, however, does not exhaust the potential variables which may be arguments of the $U_{NI}$ function. For example, the secular (as distinct from cyclical) variation in the wage structure may be positively related to $U_{NI}$. If all firms were to pay identical wages (adjusting for worker quality), workers would accept the first job opening and would have little incentive to wait for a "better" job. If, for a variety of institutional reasons, some firms pay higher wages than others, workers may prefer to be "frictionally" unemployed on the queue of the high wage sector. (This unemployed group includes those on lay-off from the high wage sector.) The postwar widening of the wage structure makes it increasingly profitable for some workers to remain unemployed on the queue of the high wage sector rather than accepting employment in the low wage sector, thus increasing $U_{NI}$. (See, for example, Robert Hall and Stephen Ross and Michael Wachter.)[3]

[1] See, for example, Martin Feldstein, Finis Welch, and Jacob Mincer. The impact of changes in the relative population of young workers on their income is discussed in Richard A. Easterlin.

[2] The method for calculating $U_{NI}$ is described in detail in M. Wachter (1975). If one accepts the notion that $U_{NI}$ is stable only in the short run, then its current high level need not persist. The demographic trends are favorable in that the percentage of teenagers in the population has already peaked and the average worker will be moving into an age category which typically has less mobility and long job attachments. My projections using fixed participation rates suggest a decline in $U_{NI}$ over the next ten years—slightly greater than its rise over the preceding ten years—to approximately 4.5 percent.

[3] A very different approach to the issue of identifying $U_{NI}$, which also stresses its unstable character,

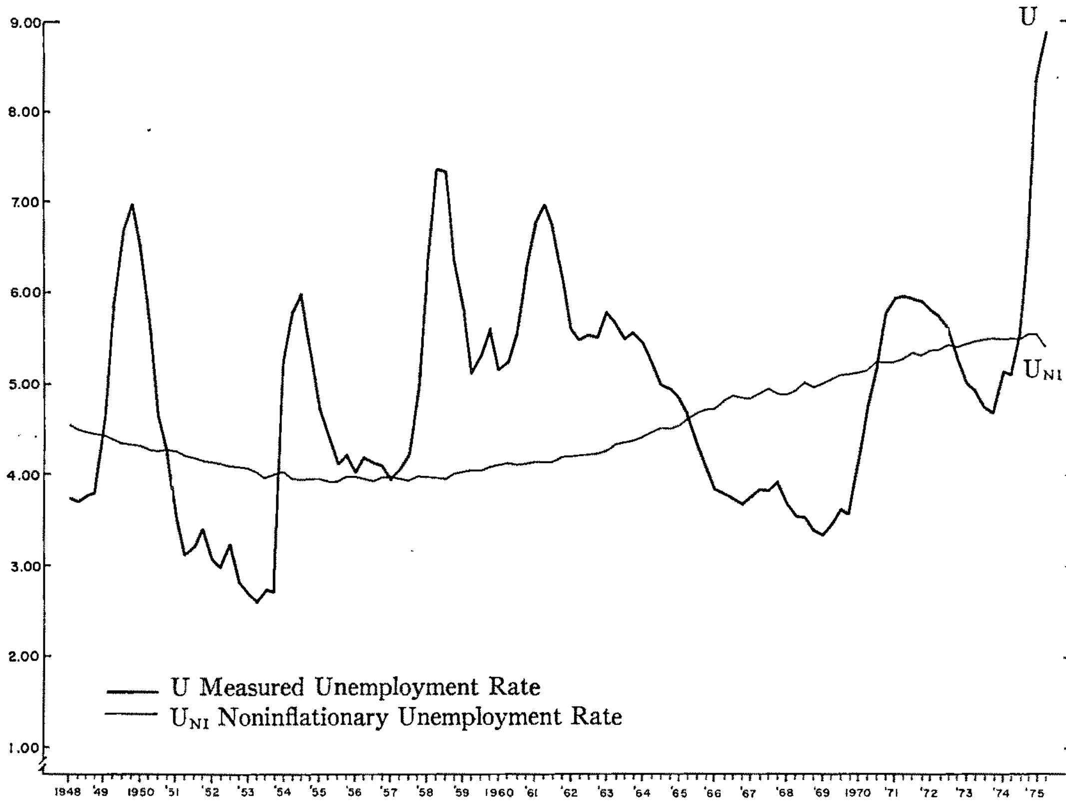

FIGURE 1

In summary, then, if the natural or the noninflationary unemployment rate were constant over time, there would be few problems in estimating the rate on the basis of time series wage data. However, it appears not only that $U_{NI}$ is a variable, but also that it is difficult to predict. The uncertainty over the level of $U_{NI}$ represents a serious problem facing stabilization policy.[4] In fact, one can argue that the major cause of the current inflation was a miscalculation of $U_{NI}$ in 1967–69 and again in 1972–73. Specifically, during 1967–69 the trade-off view was almost uniformly accepted, with the result that an unemployment rate well below 4 percent was adopted as at least a short-term target. The cost was presumed to be a somewhat higher but stable rate of inflation. In 1972–73, on the basis of government policy and pronouncements, it seems likely that the $U_{NI}$ rate was assumed to be approximately 4 percent rather than the

appears in some of the recent rational expectations models. In the Thomas Sargent and Neil Wallace model, quarterly movements in $U_{NI}$ may be calculated from an autoregression of $U_t$ and past values of $U_{t-i}$. That is, $U_{NI}$ is only separated from measured unemployment by an error term. This defines $U_{NI}$ in a purely statistical manner and does not attempt to attribute particular economic causation to the variation in $U_{NI}$. In this "superneoclassical" framework systematic monetary and fiscal policy are powerless to alter the unemployment rate. The reason is that the short-run Phillips curve (as well as the long-run curve) is vertical. Hence, only "surprises" in policy can alter the measured unemployment rate.

[4] This brief summary has omitted the possibility that even in the long run the Phillips curve is not vertical, hence $U_{NI}$ is not a single number at any point in time. Nonvertical long-run trade-offs appear in James Tobin, where stochastic disturbance leads to constant market disequilibrium, and Stephen A. Ross and Wachter, where institutional contracts are not perfectly indexed on inflation.

5 to 5.5 percent figure indicated in Figure 1.

## II. Wage Rigidity

A second difficulty facing stabilization policy is the inflexible response of at least some wages in the economy to unemployment. Inflexibility arises from a number of factors. The most widely accepted is based on the behavior of unions where collective bargaining introduces obvious lags in the wage response pattern of affected industries. Alternatively, firms often desire to pay a wage premium even in the absence of a union. The premium gives a preferred position in the labor market, assuring the firm of a queue of available workers, and enables them to avoid altering wages immediately as labor market conditions change.

Recent models have also attributed wage rigidity to the desired ongoing relationship between firms and their work forces.[5] For example, this may arise when the job content of the firm is idiosyncratic as a result of job specific training. As a consequence, most jobs in these high wage firms do not have a direct demand and supply component external to the firm. Rather, the jobs are part of the internal labor market of the firm where they are connected through a series of promotion ladders which have their own rules to provide enforcement and information on how the "market" works. Wages on each job are set as part of the internal wage structure of the firm. External market wages do not set any individual firm wages; rather the external market impinges on the firm by influencing the availability of new workers and the quit rate of old workers. Promotions and specific training, rewarded by the internal wage structure, mean that the opportunity wage of workers is below their current wage and this discourages mobility. Firms are reluctant to try to capture the discrepancy, lest it encourage costly mobility of trained workers and because of the need to encourage workers to utilize and learn the specific (and general) knowledge needed for different positions along the promotion ladder. The ongoing relationship results in firms paying a wage premium above the opportunity wage of their specifically trained workers. This premium gives firms the ability to ignore short-run market forces.

In all of the above models, wage premiums and the resulting wage rigidity arise because of the existence of institutions based on long-run commitments which are not responsive to short-run economic stimuli. As distinct from neoclassical search models, the rigidity is not based on the problems that rational workers and firms have in trying to guess the present and near term nominal and real wage levels. Rather, it is due to the fact that firms and workers cannot have all of the necessary information on the future states of the world, including fluctuations in aggregate demand policy, when they establish their contractual and institutional arrangements. Indeed, the very purpose of these institutions is to allow firms and workers to cooperate without having to sign contracts which would detail their responses to all of the potential future contingencies that might arise. These models may well be rational, in the current use of that term, but only over the long horizon during which full recontracting occurs.

The institutional nature of these models has led some to suggest that wages are not just inflexible, but rather are not determined by demand factors. For example, unions are influenced by the settlements won by other unions as part of a cost-push

[5] There is a growing literature in this area. See the summary statement by Robert J. Gordon. The discussion in the text follows Okun and Oliver Williamson, Wachter, and Jeffrey Harris.

process. This seems to be supported, in part, by recent empirical results on wage-price equations. The equations appear to show that wages depend largely on past prices and/or wages and only slightly on unemployment. Prices, in turn, depend upon cost variables. Since the cost variables are essentially prices (with wages being the most significant single price) the system reduces to a highly autoregressive model with unemployment or demand seemingly having a minor role to play.[6]

My argument is that this view of the inflation process is based on a very narrow interpretation of the data and is not in keeping with the underlying causes of wage rigidity discussed above. Even in the traditional structural wage equation where wage inflation is a function of unemployment and lagged price (or wage) inflation, the autoregressive price term should be viewed as a distributed lag generator of past conditions in the labor market. That is, lagged prices reflect expectational effects, or more generally, inertia effects in the labor market. For example, in the unionized sectors and in the internal labor markets where wages are set at discrete intervals, the economy-wide price or wage history over the fixed period of individual firms provides those firms with information on labor market conditions between their own wage changes. As a result, the feedback response through the lagged price (or wage) variable is central to the question of the magnitude and speed with which wage inflation responds to demand variables. Recessions alter inflation not only by moving the economy along a given Phillips curve, but also by causing that Phillips curve to shift downward over time. Indeed, it is difficult to separate, on both a theoretical and an empirical level, movements along and shifts of the Phillips relationship. Where the direct unemployment effect ends and the induced shift of the curve begins is largely a definitional question.

Supporting evidence for this interpretation can be found by replacing the distributed lag on prices with a distributed lag on money supply changes. The two equations have similar overall statistical fits. However, whereas lagged prices can be interpreted in a purely autoregressive framework, the money supply term more clearly reflects aggregate demand forces. Hence, one can estimate a quasi-reduced form Phillips curve which contains the discrepancy between measured unemployment and $U_{NI}$ and a distributed lag on money growth. The results indicate a short-run downward sloping Phillips relationship and a long-run wage inflation which is homogeneous of degree one in money growth. (More specifically, the long-run coefficient on the money supply is below unity but not significantly below unity. The same is true for the long-run coefficient on the price term.)

The conceptual problems in the long lags are reasonably simple, but they do create difficult policy situations. In particular, the political goal of significantly less inflation cannot be achieved quickly, and, indeed, the wage inflation rate may act in a perverse manner in the short run, depending upon the structure of the lags and the recent heritage of price inflation. That is, even though wage inflation is ultimately a function of aggregate demand,

[6] Those who espouse the nearly horizontal Phillips curve or the exogenous inflation rate also tend to be those who believe that the full employment, unemployment rate is considerably below the rate indicated in Figure 1. If one views $U_{NI}$ as being low, perhaps 4 percent, then the inflation since 1970 must largely be due to exogenous elements. As a consequence of long lags, some of today's inflation could certainly be due to the period preceding 1970 when unemployment rates were below 4 percent. But with unemployment above 4.5 percent since 1970, it is difficult to explain the current high rate of inflation without believing that $U_{NI}$ is greater than 4.5 percent *or* that inflation is an autoregressive process independent of excess demand.

much of the short-run variation in inflation is due to the past history of excess demand and not to the current unemployment rate. This creates a political dilemma as was seen in 1971 and may well appear again in 1976. In the midst of a period of high or rising unemployment, the slow downward movement of the wage inflation is very unwelcome. It does, however, correctly signal the nature of the problem. The wage adjustment is slow because demand factors take a long time to work completely through the complex institutional arrangements in the labor and goods markets. It is, however, lagged demand that is locked into the heritage or inertia effects, and these forces cannot be repealed by simply relabeling them as predetermind lagged price effects.

### III. Cost-push Inflation

The third element in the current debate over wage stabilization policy concerns the role of cost-push wage inflation. This is closely related to the previous issue of the exogeneity of the rate of wage inflation. In a sense, cost-push inflation may be viewed as one economic explanation for the autoregressive view. Unfortunately, cost-push inflation has often been defined in the past as simply the wage increases which occur when the economy is in a recession. That is, "costs" rather than "demand" are pushing up wages. If, however, the supposed cost-push phase is simply the lagged demand-pull forces working in the high wage or slow response sector, this definition is not useful in that it is devoid of policy implications.

As I have suggested elsewhere (1974), an alternative definition of cost-push can be based on changes in the relative wage structure. Specifically, the offending cost-push sectors would be those that have been secularly increasing their wage differentials, after correcting for the predictable cyclical fluctuations in the wage structure. In this definition, cost-push is not simply a lagged manifestation of demand-pull inflation, but is rather a nondemand or "exogenous" element. The union-oligopoly sector in manufacturing, which is most often labeled as cost-push, exhibits a clear cyclical pattern in its wage differential over the competitive sector but little secular rise. There are several sectors of the economy, however, which have for some time exhibited rising secular wage differentials. The two long-standing candidates are the various sectors of the government, federal, state, and local, and the construction industry. A more recent entry is the transportation and public utilities sector.[7]

The presence of cost-push inflation, defined by an increasing wage premium in certain sectors, is to reduce the attractiveness of aggregate demand policies. First, as mentioned above, cost-push may increase $U_{NI}$. Secondly, it will have a direct wage effect which may appear as an increase in the constant term or the coefficient of the autoregressive term of the short-run curve. The magnitude of the cost-push problem, however, is easily overstated. Although an important proportion of the economy is involved in the process, I argue that only their wage premium increases should be included.[8]

This sector approach to the cost-push issue also suggests an additional policy instrument for wage stabilization which can take some of the social cost out of the "recession cure." The cost-push sectors in the *U.S.* economy have been troublesome

[7] See Robert E. Hall for a more detailed discussion of the wage problem in what he calls the "nonentrepreneurial sector."

[8] To measure the full impact of cost-push pressures necessitates some method for including spillover effects. A more important issue, however, is that ongoing cost-push inflation must essentially be ratified by the monetary authorities and hence is indistinguishable from traditional demand inflation. Due to space limitations other types of exogenous shocks to the wage process, besides cost-push factors, are not discussed.

for some time. The reason is that they have highly inelastic labor demand functions, in part due to "favorable" government legislation which affects these industries directly or indirectly. They have thus been able to afford an increasing wage premium with little effect on employment. Although there has recently been some erosion of government employment protection in the state and local government sectors and in construction, the longer term trends are still unclear. What is needed in the cost-push labor markets are sector-specific, structural programs which will augment competitive demand forces.

## IV. Conclusion

To summarize, I have discussed the impact of three potential problems that confront policy makers in attempting to control wage inflation. First, the difficulty in estimating the noninflationary unemployment rate, is a very real problem. In fact, I would argue that incorrect $U_{NI}$ targets over the past decade explain an important part of the current inflation problem. Secondly, wage inflexibility is essentially a political rather than an economic problem. Wage inflation does respond to aggregate demand but with reasonably long lags due to institutional arrangements in product and labor markets. Thirdly, cost-push inflation is generally ill-defined so that it is difficult to classify. I argue, however, that it is best defined and dealt with on a sector-specific basis. As such, it is not a problem for aggregate demand management.

# Inflationary Tales Told by Static Models: The Case of Price Setters

*By* GEORGE A. AKERLOF*

Macroeconomic analysis has rediscovered the disequilibrial method of the Swedish economists. According to this analysis *ex ante* decisions are made in period t to be carried out in the next period t+1. In most models using the disequilibrial method, *ex ante* decisions have only concerned quantities. Yet, as Swedish economists were aware in the 1930's (see E. Lindahl) and as is implicit in all econometric models with wage and price equations, in a world of price-setters these decisions at time t will concern prices as well as quantities at time t+1.

The disequilibrial method is particularly easy to apply to prices. Since the *ex ante* decisions of different economic agents may be mutually incompatible (for example, *ex ante* savings may not equal *ex ante* investment), disequilibrial models must also specify the mechanism whereby the potentially conflicting *ex ante* decisions are translated into *ex post* reality. Typically, no single mechanism is obviously superior to all others. For example, the usual Keynesian model, in which unintended inventory accumulation is the difference between *ex ante* savings and investment, is only one of several equally plausible models. In contrast, there is a single most natural relation between *ex ante* and *ex post* prices: that the *ex post* nominal price equal the *ex ante* nominal price.

The equivalence of *ex ante* and *ex post* nominal prices does not mean that all price setters are satisfied *ex post*. On the contrary, given a rational world, economic agents make plans regarding relative prices; since the agent controls his own price, but not the price of other agents, he may still be disappointed *ex post* with relative prices, despite equality of *ex ante* and *ex post* nominal prices. This disappointment, by our theory, is the spur to continued inflation, given constant demand and constant expectations regarding the rate of inflation.

## I. Ex Post Inflation and Ex Ante Price Behavior

Let $\psi$ be a price index. $\psi$ is by definition a function, homogeneous of degree one, $\psi_t=\psi(p_{1,t}, \cdots, p_{n,t})$ where $p_{i,t}$ is the price of good $i$ at time t. Let there be an expected rate of inflation, denoted $\gamma^e$, which is uniform for all economic agents. Suppose that at time t the *ex ante* real price of good $i$ is $(p_i/\psi)_t^D$. The equality of *ex post* and *ex ante* nominal prices yields:

$$(1) \qquad p_{i,t+1}/\psi_{t+1}^e = (p_i/\psi)_t^D$$

where superscript $e$ denotes "expected"; and then

$$(2) \qquad \psi_{t+1}/\psi_t = \psi(p_{1,t+1}, \ldots, p_{n,t+1})/\psi_t$$

$$(3) \qquad = \psi((p_1/\psi)_t^D, \ldots, (p_n/\psi)_t^D) \cdot (1+\gamma^e).$$

In simple Keynesian economics the fundamental equation relates *ex post* income to *ex ante* investment and savings decisions. Equation (3) shows how *ex post* inflation is related to *ex ante* pricing decisions.

The theory of inflation is complete with determination of the *ex ante* decisions

* Associate Professor, University of California, Berkeley, and Visiting Research Associate, Federal Reserve Bank of New York. The author would like to thank Karl Shell, David Cass, Bent Hansen, and especially Thomas Rothenberg for valuable comments.

$(p_i/\psi)^D_t$. Each decision is pictured as the outcome of a bargain made by a small group of collusive agents. Tracing through the variables exogenous to this bargain reveals the dependency of the $(p_i/\psi)^D_t$.

The group of colluders, which may set the prices only of goods, or only of factors, or of a mixture of the two, collusively choose their expected prices so as to maximize a function $B$ of their individual utilities $U_i$. Taken over the range of possible functions $B$ and utility functions $U_i$, this specification embraces most standard bargaining solutions.

According to standard assumptions, $U_i$ is pictured as dependent on the quantity of good or factor $i$ sold by agent $i$, on the real price received, and on its real cost of production (if any)—with demand, in turn, dependent on real prices, on parameters describing tastes and tax structure and on the three variables summarizing government macropolicy (real balances $M/\psi$, real government expenditure $G/\psi$, and real taxes $T/\psi$), and with cost dependent on real factor prices, on output, and on parameters describing the structure of technology and taxes.

At time t real prices are chosen to maximize the expected value of $B$ at time t+1. We deal with expectations by assuming that $B$ and its direct and indirect arguments, such as utilities, demands and costs, in turn depend on the expectations of their arguments, of which the most important, in this regard, are expected real prices of goods and factors. Because bargains are made concerning real variables, it is reasonable (although not necessary for rationality) that expectations, likewise, concern real (rather than nominal) variables. Accordingly, expected real prices, by assumption, depend upon the expected real prices of the colluders, which are endogenous; and they depend also, because of adaptive expectations and real-world stickinesses, on the real price vector at time t, which is exogenous.

Denote the parameter vector describing tastes, etc., by $\alpha$, and the real price of factor $j$ at time t by $(w_j/\psi)_t$, and recounting the variables exogenous to the maximization of $B$:

$$(4)\quad (p_i/\psi)^D_t = F_i(\ldots, (p_k/\psi)_t, \ldots, (w_j/\psi)_t, \ldots; (M/\psi)^e, (G/\psi)^e, (T/\psi)^e; \alpha).$$

Since there is no formal distinction between bargains involving goods and bargains involving factors, *ex ante* real factor prices $(w_j/\psi)^D_t$ are functions of the same arguments.

Equations (3) and (4) divide the study of inflation into three parts: the first is the functions $F_i$, the second is the behavior of relative prices and demand, and the third is the expectations term $\gamma^e$. Study of the incidence of exogenous changes on relative prices can, by this theory, be fed into the functions $F_i$ and weighted by $\psi$ to examine the incidence of such shifts on $\psi_{t+1}/\psi_t$. These are our inflationary tales told by static models, of which the next section gives four simple illustrations.

## II. Illustrations

### A. *Example I*

As the simplest example, consider an economy of monopolistically competitive firms which share demand according to the demand function:

$$(5)\quad D_i = (p_i/\psi)^{-\mu} X^D(M/\psi, G/\psi, T/\psi),$$

where $X^D(\cdot, \cdot, \cdot)$ is the real demand per firm associated with the macropolicy $(M/\psi, G/\psi, T/\psi)$, and the parameter $\mu$ is greater than one. Each firm has a production function for its output: $Q = K^\beta L^{1-\beta}$, where $K$ is capital and $L$ is labor. Profit maximization and monopolistic competition, with constant real wage expectations and capital considered a fixed factor, yields:

$$(6)\quad (p_i/\psi)^D = [\{(w/\psi)\mu(\mu-1)^{-1} \cdot (1-\beta)^{-1}\}^{1-\beta}(X^D/K)^{\beta}]^{1/(\beta\mu+1-\mu)}.$$

In this economy, (6) multiplied by $(1+\gamma^e)$ gives $\psi_{t+1}/\psi_t$ by (3), since all firms are the same.

Formula (6) illustrates in particular what formulas (3) and (4), taken together, suggest more generally. Formula (4) lists the factors involved in the desired readjustment of relative prices: demand and relative prices themselves. Formula (6) suggests that policies with high incidence on real factor prices typically lead to reduced inflation—demand and $\gamma^e$ being constant.

As one application, formula (6) and others similarly derived predict how much inflation will occur if price controls are imposed and then suddenly removed. The inflation will be positively related to $(w/\psi)$, $X^D$ and $\gamma^e$, and negatively related to $K$. The old-wives' tale is commonly believed that wage and price controls inevitably lead to suppressed inflation, which, on removal of the controls, results in a fresh inflationary outbreak; formula (6) multiplied by $(1+\gamma^e)$ indicates the degree of suppressed inflation as well as its functional dependence.

### B. *Example II*

(1) *Question.* Tax collections being of such large magnitude, shifts in tax structure, if they affect costs but not demand, constitute a practical means of reducing inflation while keeping employment constant. The next three examples illustrate the type of tax shifts which reduce inflation. The first example concerns an upward shift in the income tax and a downward shift in the sales tax of equal amount, so that disposable income, and therefore, demand, is left constant.

(2) *Model.* Let the economy be composed of similar firms, with demand for each firm depending on the price to the consumer $p$, the prices charged by other firms $\psi$, real balances $M/\psi$, real government expenditures $G/\psi$, and real taxes $T/\psi$. The firm has a real cost function, dependent on the cost of hiring labor (which is dependent on the real wage denoted $\omega$), the real cost of materials obtained from other firms, equal to 1, the real price of raw materials (denoted $\rho$), and the sales tax on output at rate $\tau_s$. (Taxes enter the cost function since they are as much a cost of selling the product as the cost of any input.) Furthermore, firms have static expectations regarding real factor costs.

Entering the relevant variables into equation (4), multiplying by $(1+\gamma^e)$, and putting the product in differential form for convenience of notation, yields:

$$(7)\quad d\ ln\ \psi/dt = \delta[F(\omega, \rho; M/\psi, G/\psi, T/\psi\ \ \tau_s) - 1] + \gamma^e,$$

where adjustment coefficient $\delta$ enters because the length of period in difference equation (4) was unspecified. $\rho$ is taken to be a parameter determined exogenously in international markets. To track inflation in excess of $\gamma^e$ it remains to track the path of $\omega$.

Econometricians have typically specified two forms of wage equation. In the first type, due to Phillips, the expected change in the real wage is a concave function $f$ of the rate of unemployment $u$. The second type of wage equation, due to Edwin Kuh, says that the expected change in the real wage depends upon the gap between a target real wage $\omega^*$ and the actual real wage. $\omega^*$ may depend upon real variables—the sales tax and income tax (denoted $\tau_y$) among them. There being no conclusive evidence to favor a wage equation of either one form or the other, we propose the combination:

$$(8)\quad d(ln\ (w/\psi)^e/dt = \lambda(\omega^*(\tau_s, \tau_y) - \omega) + f(u).$$

Subtraction of (7) from (8) yields the differential equation for $\omega$:

$$(9)\quad \dot{\omega}/\omega = \lambda(\omega^* - \omega) + f - \delta(F - 1).$$

(3) *Result.* Our method consists of looking at the incidence on relative prices of some exogenous shift and using equations (3) and (4) to determine the effect on inflation. The incidence of tax shift on $\omega$ between steady states with constant $\omega$ is implicitly defined by (9); inflation is given by (7).[1] Demand, and therefore $u$, is unaffected by the shift in tax structure. Therefore we calculate the shift in inflation between steady states with constant $\omega$ and with $d\tau_s = -d\tau_y$:

$$(10)\quad \frac{d(\dot{\psi}/\psi - \gamma^e)}{d\tau_s} = \delta\lambda\left(\frac{\partial F}{\partial \tau_s} - \frac{\partial F}{\partial \omega}\frac{\partial \omega^*}{\partial \tau_y} + \frac{\partial F}{\partial \omega}\frac{\partial \omega^*}{\partial \tau_s}\right) \Big/ \left(\delta\frac{\partial F}{\partial \omega} + \lambda\right).$$

Interpret $\omega^*$ as the *ex ante* real wage. Formula (10) says that the change in inflation due to the shift in tax structure has the same sign as the increase in *ex ante* price directly due to tax changes ($\partial F/\partial\tau_s$) plus the increase in *ex ante* factor prices due to the tax changes ($-\partial\omega^*/\partial\tau_y$ and $\partial\omega^*/\partial\tau_s$) weighted by their effects on *ex ante* prices (weight$=\partial F/\partial\omega$).

Formula (10) gives a sensible result regarding the effect of the decrease in the sales tax *cum* increase in income tax. Remember that $\omega$ is the before-tax wage to the worker divided by the after-tax price. If the increase in income tax causes an equivalent increase in *ex ante* wages $\omega^*$ and if the pass-through of wage costs and sales taxes are equal, the inflationary effect is nil (assuming also $\partial\omega^*/\partial\tau_s=0$). The incidence of the tax shift on *ex ante* real factor cost determines whether the shift in tax structure is inflationary or deflationary. Thus our example illustrates the earlier assertion that shifts in structure tend to be inflationary or deflationary as their incidence on factor costs is positive or negative. (In other problems demand may shift, and it also must be considered.)

Formula (10) also shows the type of information, with this model, needed to predict changes in inflation due to tax structure. Most important is the effect of tax changes on intended bargains to know whether the shift in tax structure is inflationary or deflationary. Professional labor arbitrators, whose job is to know how different variables affect intended contracts, must, at least on a case-by-case basis, have informed opinions regarding the extent to which intended bargains concern before-tax or after-tax wages.

### C. *Example III*

To examine further the relation between inflation and tax structure, consider the impact of an equal fall in the sales tax and rise in the real cost of a raw material input used in fixed proportions. In the previous example, since the cost function is symmetric in the sales tax and the cost of such raw materials, and since it should be a matter of indifference to the wage equation whether additional payments are made to governments or to producers of raw materials, the equal and opposite changes in $\tau_s$ and in $\rho$ do not affect inflation through costs, but only through their unequal effects on demand. The raw materials producers, whether domestic or foreign, will increase their demand because $\rho$ has risen, whereas the fall in $\tau_s$ will result in no compensating reduction in government demand. (To other producers and to factors of production, the direct effects on income of the rise in $\rho$ and fall in $\tau_s$ are offsetting, and therefore their demand is unchanged.)

The properties of an "ideal tax" are now clear: such a tax would reduce demand without affecting the costs on which $(p_i/\psi)^D$ are based. Additional imposition of a tax of this sort could return the economy to the previous demand without additional

[1] Bent Hansen has called such steady-states "quasi-equilibria."

inflation. Generally, with such a tax, appropriate tax-*cum*-subsidy schemes can achieve *any* level of demand with *any* level of inflation. Economists have models in which the profits tax, the land tax, and the poll tax, accordingly, do not influence the cost-base of $(p_i/\psi)^D$. In contrast, in the last example, increases in the income tax added to $\omega^*$ and therefore indirectly to costs.

### D. *Example IV*

As a final example, consider a different industrial structure, in which firms and unions jointly set prices and wages to maximize the product of their utility functions (the Nash bargaining solution.) Let the utility of firms be proportional to profits. Let demand be as given in Example I, with production function $Q=L^{\epsilon_2}$, and with raw material requirements costing $\rho$, in real terms, per unit of output. Let utility of unions $V$ depend on wages and employment as $V=\omega^{\nu}L^{\epsilon_2}$. We find:

$$(11)\quad (p/\psi)^D = \frac{\rho}{1-\tau_s}\left(\frac{\epsilon_1+\epsilon_2}{1+\epsilon_1} - \frac{\nu}{1+\nu}\right) \cdot \left(\frac{\mu\epsilon_1 + (\mu-1)\epsilon_2}{(1+\epsilon_1)} - \frac{\nu}{1+\nu}\right)^{-1}.$$

As one result, note that a parallel calculation shows $(p/\psi)^D$ independent of the profits tax: the sales tax is more inflationary.

## III. Conclusion

This paper has given a method, illustrated by four examples, whereby inflation can be derived from microeconomic structure. This method is useful in determining how shifts in this structure cause shifts in inflation. Such examples are important, both to understand the assumptions made by econometricians, who implicitly use the Swedish method, and also to appreciate the range of possible conclusions to be derived from plausible microeconomic systems.

# SAVINGS BEHAVIOR: NEW INFLUENCES AND CONSEQUENCES

# Social Security and Saving: The Extended Life Cycle Theory

By MARTIN FELDSTEIN*

The life cycle model is the central idea in the modern theory of saving because it provides the crucial link between the microeconomics of rational household behavior and the macroeconomics of the rate of saving. The fundamental insight of this theory, that aggregate saving is positive in a growing economy because the younger workers who save are more numerous and have higher earnings than the older retirees who dissave was presented by Sir Roy Harrod in the second lecture of his famous book, *Towards a Dynamic Economics* (1948). Harrod's description of the household's optimizing behavior, which he notes is an extension of Irving Fisher's (1930) analysis, is remarkably modern and "neoclassical" for someone who is rightly regarded as one of the great developers of Keynesian economic theory. But it was Franco Modigliani and his collaborators (e.g., 1954, 1957, 1963, and 1966) who developed Harrod's metaphor of "hump saving" into a quantitative theory and began the process of empirical verification that has made the life cycle model a central feature of our current economic understanding. Today I want to discuss an extension and verification of the life cycle model and its aggregate implications to include social security, the most important form of "saving" for the majority of American families.[1]

Social security tax "contributions" in the 1974–75 fiscal year were $83 billion, approximately equal to the $85 billion of personal saving and nearly 75 percent of total private saving (including corporate saving). I recently estimated that social security "wealth" (i.e., the actuarial present value of the future social security benefits of the current adult population) was more than $2 trillion in 1971 and thus nearly 60 percent of all other household assets (Feldstein 1974a). To ignore social security in the theory and testing of saving behavior is therefore to omit a factor of fundamental importance. Moreover, social security wealth is an exogenous variable that can in principle provide a better test of the life cycle hypothesis than is possible with the traditional measure of wealth.

## I. The Extended Life Cycle Model

The familiar life cycle model emphasizes the process of saving during working years for consumption during retirement. An important assumption of this model is that the period of retirement is fixed:

* Professor of economics, Harvard University, I am grateful to the National Science Foundation for its financial support.

[1] Theories and empirical tests have ignored the existence of corporate saving which now accounts for more than 40 percent of net private saving. I have examined the impact of corporate saving on total private saving (Feldstein 1973; Feldstein and Fane 1973) but will not discuss the results of those analyses in the current paper.

changes in wage rates, wealth or other variables may alter the allocation of lifetime consumption between working years and retirement years but they do not change the allocation of the years themselves between work and retirement.

The assumption of a fixed retirement period conflicts with observed behavior and has unintentionally caused some important evidence to be incorrectly interpreted as conflicting with the basic notion of rational life cycle saving. In 1900, only 37 percent of men over age 65 were retired; by 1971, this had doubled to 74 percent. It is appropriate therefore to extend the life cycle model to make the period of retirement endogenous.

A general formulation of such a model would have the individual choose both labor supply and consumption every year. A restricted specification, more in the spirit of the original life cycle model, would define a "preretirement period" during which the individual's labor supply is fixed and a "retirement period" during which the individual can vary his labor supply. The individual's preretirement consumption and saving and his "retirement period" labor supply would then be optimized together. In this extended life cycle model, the change in any endogenous variable has two separate effects on saving: first, it changes saving directly as it would in the traditional life cycle model, and second, by changing retirement, it alters saving indirectly.

Consider the example of social security. In the traditional life cycle model, the introduction of a public program that provides retirement benefits unambiguously reduces the amount of personal saving. However, in the extended life cycle model, there is a second effect of social security that tends to increase personal saving. By providing transfer payments to older persons who retire, social security induces the aged to reduce their supply of labor. This reduction in working years and the resulting increase in the period of retirement induce additional saving. The net effect of social security on the saving of the non-aged is indeterminate and depends on the relative strength of the traditional "saving replacement effect" and the new "induced retirement effect."[2]

There is a further reason, although one which I consider to be much less important, why the effect of social security is theoretically indeterminate. Robert Barro (1974), Levis Kochin (1974), and Merton Miller and Charles Upton (1974) recently presented an alternative extension of the life cycle model with very different implications about the effect of social security and of public debt. The novel feature of these models is the presence of planned bequests and the assumption that each individual's utility depends not only on his own consumption but also on the utility of all future generations. Although the introduction of social security creates wealth for the current generation, it also creates a liability (according to these authors) for a future generation or generations. The current generation, according to this theory, will resist this redistribution from their heirs to themselves by increasing their bequests by just enough so that their heirs are no worse off. The extra saving for this bequest just offsets the reduced saving that would otherwise be associated with the creation of social security benefits.

Although I think this model is ingenious, I find the analysis unconvincing in its argument that social security should have no effect on private saving.[3] First, the

[2] The extended life cycle model was presented in Feldstein (1974a). A formal proof that an increase in social security benefits may actually increase saving if the extent of retirement is endogenous is presented in Feldstein (1974b).

[3] I have developed the following criticism more fully in Feldstein (1975b).

theory is formally correct only if the social security program does impose a future liability exactly equal in present value to the wealth that is created for the current generation. Such a liability will be imposed only if the social security program will be abolished at some date in the future or the economy has no growth of either population or real per capita income. In the more relevant case of a growing economy and a social security program that will last indefinitely, each future generation can receive more in benefits than it pays in social security taxes. More specifically, in a steadily growing economy the individual earns on his social security taxes an implicit "rate of return" that is equal to the rate of growth of the tax base. If this rate of growth were equal to the marginal product of capital, every future generation would be as well off participating in social security as it would be otherwise; in this case there is no future liability at all.[4] In the more realistic case in which the rate of growth is less than the marginal product of capital, the current social security wealth entails a future liability with present value equal to some fraction of the current social security wealth. Thus, even with this extreme form of rationality, the social security program would represent net wealth and should have a depressing effect on saving if retirement is fixed.

This form of analysis ignores the effect of personal and corporate income taxes. The individual does not earn the marginal product of capital on his saving but a substantially lower rate of interest. The implicit "rate of return" on social security tax payments (i.e., the growth rate) may well equal or exceed the real after-tax rate of interest earned by most of the population. If the individual makes *this* comparison, he may well conclude that social security will provide a net gain for all of his future heirs. Instead of increasing his bequest, such an individual might actually decrease it. To avoid this mistake, the farsighted individual must recognize that the national reduction in real saving that follows the introduction of social security will lower the future capital stock which will in turn reduce future income tax collections and lower future real wage rates. In these indirect ways his heirs will be made worse off.

The complexity of these anticipations casts doubt on the empirical relevance of this entire exercise. To make the "correct" offsetting adjustment to his bequest, the typical individual must understand the effect of his bequest and of the social security program on all future generations and must assume that all of his future heirs will share his farsightedness. The individual must also understand the general equilibrium effect of reduced aggregate saving on future wages and taxes. Since the economics profession has previously ignored the need to adjust bequests to compensate for future tax liabilities, it may be safe to assume that the typical household has also not made the adjustment implied by the new theory.

Finally, it is clear that for most families bequests are very small and may even be unintentional. The typical voluntary "intergenerational transfers" are not bequests at death but the support of the consumption that their heirs enjoy as children. The nature of these transfers makes it even less likely that households will respond as the theory suggests. Moreover, if households do respond to an increase in social security by increasing such intergeneration transfers, this merely changes the nature of the individual consumption and does not constitute a transfer of real capital.

At most, therefore, the new emphasis

[4] This point was implicit in Paul Samuelson (1958) and developed explicitly by David Cass and Menachem Yaari (1967).

on rational bequests provides a further reason why the traditional life cycle model overstates the likely effect of social security on saving. The actual effect, i.e., the balancing of traditional wealth replacement, induced retirement, and increased bequests, is an impirical question. However, before turning to the econometric evidence, I must comment on the radical theory that Paul David and John Scadding (1974) recently presented.

The starting point for David and Scadding was the finding by Edward Denison (1958) that the gross private saving rate, i.e., the ratio of private saving plus depreciation to gross national product, was the same in 1929 and in the high employment years between 1948 and 1956. David and Scadding show that if Denison's ratio is modified by adding the purchase of consumer durables to gross private saving and by adding the gross imputed rental flow of consumer durables to *GNP*, the new ratio shows no trend during the period since 1900.

Although I think it is impossible to provide any direct behavioral model that relates gross saving to *GNP* and ignores all taxes, David and Scadding attempt to do just that. According to their theory, households treat all government expenditure financed by taxes as equivalent to private consumption and thus substitute tax-financed government expenditure for consumption with no change in saving; in contrast, households regard all government expenditures financed by government debt as equivalent to private investment and therefore allow each dollar of government debt to crowd out one dollar of private debt, i.e., private saving is again unchanged. In addition, David and Scadding offer no explanation of why households are concerned with *gross* saving instead of subtracting depreciation to obtain the real accumulation of wealth, a very important difference in establishing the stability of their saving ratio. Finally, by a stroke of poetic license, they describe this combination of implausible assumptions as a model of "ultrarationality."

While I believe that this specific theory of ultrarationality is unacceptable, the statistical evidence of a trendless saving ratio deserves comment. It is tempting to think that even if no acceptable theoretical explanation is available now, the stability of the saving ratio is too unlikely to be due to chance. But is it? The adjusted gross private saving ratio of David and Scadding, i.e., the ratio of private saving as normally defined plus depreciation plus consumer durable expenditures to the sum of gross national product and the implicit gross rental flow on consumer durables, is only one of a great many ratios that might be examined and it is certainly not the most natural of them. In a large enough set of alternatives, one can expect to find the most unlikely things. Moreover, as Peggy Musgrave (1975) has recently pointed out, the official national income account definition of private saving ignores the very substantial saving by the wholly owned foreign subsidiaries of *U.S.* corporations, now approximately 1.8 percent of *GNP*. Since this figure represents *net* saving, allowing for depreciation would make the effect even larger.

I believe that the general long-run stability of the particular ratio studied by David and Scadding is the result of a number of offsetting forces, including the growth of taxes, the higher level of incomes, the increase in retirement and the expansion of social security. There is no reason to expect this particular stability to continue in the future.

Let me turn now to the econometric analysis of the extended life cycle model. I will start not with the new research that has been done to implement this model but with the use of the model to

reinterpret some empirical results that have puzzled economists for more than a decade.

## II. Explaining the Paradoxical Effect of Pension Coverage on Direct Savings

The extended life cycle model can resolve the apparent paradox of the finding by George Katona (1965) and Phillip Cagan (1965) that persons covered by private pensions do not save less directly and may save more than those persons who are not covered by pensions.[5] Cagan explained his surprising results in terms of a "recognition effect": when an individual is forced to participate in a pension plan, he recognizes for the first time the importance of saving for his old age. Participation in a pension plan has an educational effect: more formally, it changes the individual's utility function as he perceives it *ex ante* during his working years. Katona added to this a second explanation: the "goal gradient" hypothesis borrowed from psychological research on the forming of aspirations. According to this theory, "effort is intensified the closer one is to one's goal" (Katona 1965, p. 4). In more conventional economic terms, this would imply that individual preferences are themselves a function of the opportunity set or of the initial position, a dramatic departure from the usual assumption of economic analysis.

The extended life cycle model explains the findings of Cagan and Katona without invoking a recognition effect or a model of changing preferences. Workers who are covered by pensions have an incentive to retire earlier than they otherwise would. The pension therefore has two effects on direct personal savings: (1) It reduces personal saving because it substitutes for household assets, but (2) it also increases personal saving because it lengthens the period of retirement over which accumulated assets will be spread. Since the net effect of the pension depends on the relative strength of these two forces, there is no paradox in the empirical finding that private pension coverage does not reduce direct personal saving.

Thus, the extended life cycle model incorporates the important structural feature of changing retirement and reconciles the previously paradoxical evidence on the effect of pensions with a theory of rational savings and retirement choice. The extended life cycle model also implies that social security has an ambiguous effect on private saving that can only be resolved by empirical analysis. Let me therefore turn to the recent econometric research on this subject.

## III. Recent Econometric Studies

In the first direct test of the extended life cycle model, I examined savings behavior in the United States from 1929 to 1971 (Feldstein 1974a). The analysis employed a generalization of the consumption function specification that Albert Ando and Franco Modigliani (1963) had used to test the traditional life cycle model. I reasoned that the effect of social security was most appropriately represented by the present actuarial value of the retirement and survivor benefits to which the current adult population was entitled; I called this magnitude social security wealth. The growth and extension of the social security program has raised social security wealth from 75 percent of *GNP* in 1940 to more than 200 percent of *GNP* today.

The social security wealth variable should play the same role in the aggregate consumption function that is expected of the ordinary "fungible wealth" variable:

[5] Alicia Munnell's (1974b) reanalysis of the Cagan data in a multiple regression model found a very weak and completely insignificant negative effect of pension coverage on direct saving.

a higher level of wealth should increase current consumption and decrease current saving. In addition to this direct effect, the growth of social security wealth should increase retirement and thus stimulate saving. The coefficient of the social security variable should therefore reflect the net effect of these two influences.

The statistical estimates indicate that social security does reduce private saving. The estimated marginal propensity to consume social security wealth was generally significantly positive and not significantly different from the coefficient of ordinary wealth.[6] The implied magnitude of the effect of social security on saving is therefore very large. The point estimate of the coefficient of social security wealth indicates that personal saving in 1971 was approximately halved by social security, implying a reduction in total private saving (including corporate saving) of 38 percent. When the sample was restricted to the period since 1947, the coefficients remained quite similar but the standard errors became so large that the effects of both ordinary wealth and social security wealth were insignificant. This evidence thus provides preliminary support for the conclusion that social security substantially depresses saving, but indicates the need for research with new bodies of data that can provide more precise estimates.

The time series data was analyzed in a number of interesting ways by Munnell (1974a, b). She tested the effect of retirement explicity by modifying the conmetric rate of decline in the labor force participation of older men from 1900 to sumption function with social security wealth to allow the marginal propensity to consume out of disposable income to vary with the labor force participation of men over 65. Although this provides a very imperfect measure of the expected future retirement of current workers, the interaction variable always had the expected sign. With this method of adjusting for the induced retirement effect of social security on saving, the coefficient of social security wealth was closer to an estimate of the pure wealth substitution effect; Munnell's coefficient of social security wealth had been nearly 50 percent greater than my estimate was in an equation that did not try to separate the effect of induced retirement. Munnell's decomposition also permits explicit estimates of the way in which the social security wealth replacement effect and the general increase in retirement have had offsetting effects on aggregate saving: in 1969, according to her estimates, social security wealth reduced personal saving by $54 billion while the greater retirement since 1929 increased saving by $26 billion.[7] In interpreting these figures it would of course be wrong to regard all of the impact of the increased retirement to be the indirect induced retirement effect of social security. Much of the increased retirement would

[6] The close similarity of the two coefficients reflects several offsetting effects and should not be regarded as evidence that social security wealth is an exact replacement for private wealth. Although social security wealth has an associated retirement effect that reduces its impact, it may be important that ordinary wealth may be of less certain value, may be intended in part for bequests, and is thus subject to estate tax. Ordinary wealth is also endogenous; a sustained period in which the unobservable disturbance in the consumption function is positive will reduce wealth and the resulting negative correlation between these two variables will bias the coefficient of ordinary wealth toward zero.

[7] This calculation is based on the first equation of Table 3, p. 562 of Munnell (1974a). It differs from Munnell's estimate which is based on her strange and extremely narrow concept of "retirement saving" which she defines to include only the increase in the net assets of life insurance companies and of private and government pension plans; by ignoring most forms of saving, Munnell greatly underestimates the saving effects of both social security wealth and changing retirement behavior. Her later work (Munnell 1975) uses only the more traditional definition of saving.

no doubt have occurred simply because of higher incomes, urbanization, the decline of self-employment, the depression, etc.; a simple extrapolation of the geo-1929 can account for nearly 75 percent of the increase in retirement from 1929 to 1969.[8]

A quite different type of evidence supporting the extended life cycle model is provided by an analysis of intercountry differences in saving rates. Modigliani (1970) has shown that the pattern of intercountry differences in private saving rates is consistent with the predictions of the traditional life cycle theory: higher saving rates in countries with higher rates of economic growth and higher proportions of the population of working age. To test the extended life cycle model, I (Feldstein 1974b) added measures of retirement behavior (the labor force participation rate of men over 65 and the life expectancy at age 65) and of the substitution effect of social security (the ratio of social security benefits per aged person to average income per capita). The coefficients of these variables had the predicted signs, were statistically significant in a variety of specifications, and accounted for a substantial portion of the variation in the saving rates of the 15 developed countries in the sample. In particular, the coefficient of the social security variable implied that the average level of social security benefits reduced the saving rate by 4.2 percentage points or one-third of the average private saving rate; similarly, an increase in relative social security benefits from one standard deviation below the mean to one standard deviation above reduced the private saving rate by 5.4 percentage points.

This of course reflects only the partial wealth replacement effect of social security since retirement is held constant statistically. However, the evidence indicates that the wealth replacement effect is much more important than the induced retirement effect. The next effect of social security implies that the average level of social security benefits reduces the saving rate by 3.5 percentage points, more than four-fifths of the pure wealth replacement effect.[9]

The extended life cycle model also resolves a long-standing puzzle in the international studies of saving behavior. A common finding of these studies has been that the countries with a higher per capita income also have a higher saving rate, an apparent conflict with the long-run homogeneity of the saving rate in the time series and with the presumption of the traditional life cycle theory that the division of lifetime consumption between working years and retirement years is independent of the overall level of consumption.[10] The estimates of the extended life cycle model show that the higher saving rate in higher income countries actually reflects a higher retirement rate. Average

[8] Although Munnell estimates a saving function rather than a consumption function, this is irrelevant since only the current value of income is included. She does, however, show that the results are not sensitive to the choice between the conventional national income accounting definition of saving and a more inclusive measure obtained as the annual change in Raymond Goldsmith's (1956) measure of household wealth; she updates the Goldsmith measure with data from the Securities and Exchange Commission.

[9] Henry Aaron (1967) reported a negative correlation between social security benefits and household saving rates but later (Aaron 1968) reported that this correlation could not be confirmed with slightly different data. His original study did not use a consistent life cycle framework and no specific estimates are reported in the 1968 study. Aaron's primary interest was the hypothesis that the saving rate influences the percentage of national income spent on social insurance; he concluded that the evidence does not support this hypothesis.

[10] This has been an implicit presumption but it reflects the further assumption of homothetic preferences, and it is not a fundamental implication of the life cycle model.

income has no effect on saving when labor force participation is held constant. In contrast, higher income induces more retirement, which in turn leads to a higher rate of saving.

The use of microeconomic household data to test the extended life cycle model and to assess the impact of social security is just beginning. There are now several data sets that could provide useful information. Munnell (1975) found strong evidence that men aged 45 to 65 substantially reduce their own saving if they are covered by social security or by a private pension.[11] Her analysis used an extended life cycle model that explicitly included the expected time to retirement and life expectancy after retirement, but there was no specific test of the effect of differences in expected retirement date. Because social security now covers almost everyone (the exceptions are almost all government employees or railroad workers with their own pension programs), the estimated effect of social security coverage is difficult to interpret. It is reassuring therefore that Munnell finds that saving is reduced by private pension coverage and varies inversely with crude estimates of pension benefits and social security benefits.

The effect of social security on private saving also explains why the concentration of wealth as traditionally measured has remained stable during the past fifty years in spite of strong economic pressures toward greater equality. Simon Kuznets (1956) calculated that the top 1 percent of the population received 15.6 percent of disposable income in the 1920's but only 7.7 percent in 1946 (the last year of his analysis). Although exactly comparable figures are not available for more recent years, there is no evidence of an increasing concentration of income and some evidence that the share received by upper income families has continued to decline. In contrast, Robert Lampman's (1962) classic study concluded that the share of wealth held by the top 2 percent of families varied only from 32 percent in 1922 to 29 percent in 1953; more recent evidence shows no decrease in concentration in the 1960's. It seems at first a paradox that the concentration of wealth has remained unchanged in spite of the reduced concentration of income and the rapid increase in estate and gift tax rates. The paradox is easily resolved however by recognizing that the vast majority of middle income and lower income households have substituted social security wealth for ordinary fungible wealth. I used the 1962 Federal Reserve Board *Survey of Consumer Finances* to compare the distribution of fungible wealth (i.e., excluding social security) with the distribution of total wealth including a detailed estimate of each family's social security wealth (Feldstein 1974c). The results show that the distribution of total wealth is much less concentrated than the distribution of fungible wealth and has therefore become much more equal during the past half century. For example, the top one percent of families with a head between 35 and 64 years old owned 28.4 percent of fungible wealth but only 18.9 percent of total wealth; similarly, the top 4 percent of such families had 45 percent of fungible wealth but only 31 percent of total wealth.

This analysis of the distribution of social security wealth also provides indirect support for the traditional life cycle model. Within each age group, the distribution of income among income classes was more similar to the distribution of

[11] Her analysis is based on the National Longitudinal Survey directed by Herbert Parnes and conducted by the Bureau of the Census. Saving is defined as the change in net worth over a 3 year period.

total wealth than to the distribution of fungible wealth.[12]

## IV. Conclusion

With our current pay-as-you-go method of financing social security, the social security tax receipts are paid out as concurrent benefits and are not accumulated. When we, the current generation of workers, retire, we will not receive social security benefits by drawing on an accumulated fund. Instead, our benefits will depend on the tax payments of those who are at work when we retire. Because there is no accumulated social security fund, the decrease in private saving that is caused by social security entails an equal decrease in national saving.

The very substantial size of the estimated decrease in saving implies a correspondingly large decrease in the nation's capital stock. The parameter estimates in my study of *U.S.* time series data implied that without social security the *U.S.* capital stock would eventually be some 60 percent higher (Feldstein 1974a). The larger capital stock would mean greater productivity, higher real wage rates and a higher national income.[13] But the important implication of the reduction in saving is not the fall in income or wages per se. The reduction in welfare comes from the distortion in saving, the substitution of an asset with a very low implicit rate of return for real capital accumulation with a much higher social rate of return.[14]

[12] Although the focus of this survey is on savings, I should mention some of the recent related work that has shown that social security has a powerful effect on retirement behavior. Building on earlier work by Margaret Gordon (1963) and Henry Aaron (1967, 1968), I used a cross section of countries to estimate the effect of social security on retirement (Feldstein 1974b). Much more detailed analyses of microeconomic data for the United States have been presented by Joseph Quinn (1975) and Michael Boskin (1975).

[13] This assumes, I believe correctly, that the *U.S.* economy could absorb a higher rate of capital accumulation. The early Keynesian "secular stagnationists" saw social security as a welcome method of reducing the excess saving that they feared would cause a permanent depression after World War II; see Seymour Harris (1941).

[14] For a more general discussion of these issues, see Feldstein (1975a).

# Intergenerational Transfers and Life Cycle Consumption

*By* ALAN S. BLINDER*

It is now roughly twenty years since Franco Modigliani and Milton Friedman revived and gave empirical substance to Irving Fisher's theory of lifetime planning by the consumer.[1] This paper can be thought of as a discussion of what it means to take the life-cycle model seriously. In this spirit, Section II explores the role of intergenerational transfers and, in particular, the wealth elasticity of bequests in the aggregate consumption function. However, it would be a mistake to take the life cycle hypothesis *too seriously*. Its central message—that the lifetime pattern of consumption is independent of the lifetime pattern of earnings—cannot be literally true in a world where there is uncertainty, where working and consuming are competing uses of time, and where the ability to borrow against future earnings is severely limited.[2] Section I concentrates on capital market constraints, stressing how intergenerational transfers help determine which households are constrained and which are not. Though the orientation is clearly theoretical, the relevance to public policy cannot be missed in view of recent fiscal policy actions.

## I. Consumption Behavior of Planners and Reactors

While there are many principles according to which households can be divided, I find it useful to think of the aggregate consumption function as a weighted average of the consumption functions of two types: planners and reactors.

Planners have sufficient financial means to adhere tolerably close to their optimal consumption paths. Because borrowing constraints are not binding for them, the relevant budget constraint is based on "wealth" or "life resources," defined as the sum of discounted earnings and financial inheritances. It is easy to show that the lifetime marginal propensity to consume (*MPC*) out of wealth is positive, and is smaller than unity if there is a bequest motive.[3] A planner will spread the extra consumption permitted by any windfall gain, such as a government rebate check, over all the remaining years of his life, and probably will add some of it to his bequest. Since the short-run *MPC* depends critically on age, one good way to elicit a substantial spending response from a one-time transfer payment is to concentrate the funds on elderly households. In this light, the recent $50 per head social security bonus looks like a highly imaginative fiscal policy.

Reactors are consumer units that are prevented from pursuing their first-best optimal plans by borrowing constraints. A household which would like to spend more than its income, but is prevented from so

* Assistant Professor of Economics, Princeton University. I have benefited from helpful comments of Martin Hellwig, William Buiter and Sherman Robinson, who are not to be implicated in the conclusions. Financial support from the National Science Foundation is gratefully acknowledged.

[1] No distinction will be made between the life-cycle and permanent income models, as they are just two ways of implementing the Fisherian analysis empirically.

[2] Regarding uncertainty, see Keizo Nagatani. Regarding time budgets, see James Heckman. Regarding borrowing constraints see Tsuneo Ishikawa (1974), Thomas Russell, James Tobin and Walter Dolde, John Flemming or Clark Wiseman.

[3] See the author (1974), pp. 39–40.

doing by imperfect capital markets, will generally consume its entire income. A windfall loss, therefore, must come entirely out of consumption. A windfall gain, on the other hand, loosens the capital market constraint; so the short-run *MPC* may be high but probably will not be unity. Thus, the reactor's responses to windfall gains and losses are asymmetric.

### *A. Who Plans and Who Reacts?*

While it is tempting to think of the poor as reactors and the rich as planners, such a simple identification is not generally correct. As Tsuneo Ishikawa (1974) showed, the classification has a lot to do with the timing and volume of intergenerational transfers.[4]

The poor man with a flat age-income profile and no financial inheritance is constrained by many things but not by the inability to borrow against future receipts. The households who feel the pinch of capital market imperfections most acutely are those anticipating large cash inflows later in life—whether from high earnings or from large financial inheritances—but whose current cash inflows are insufficient to finance the consumption stream warranted by their lifetime resources.

Wealthy households which expect a substantial financial inheritance late in life when their parents die will probably be reactors for much of their lives. Then, when the inheritance is finally received, diminishing returns will dissuade them from completely making up for lost time. So capital-market imperfections will induce them to consume less and save more over their lifetimes. Of course, parents can ease these constraints by transferring wealth *inter vivos*, but this would simply shift the burden of capital-market constraints onto the parent generation as it sought to accumulate wealth at a much earlier age.

Intergenerational transfers of human capital are no doubt much more important quantitatively than are financial inheritances. Further, they have the important characteristic that children must receive them at relatively young ages if they are to do any good. Child care expenses cannot be deferred until the children are grown. College education yields small financial benefits if taken at age fifty. Since intergenerational transfers of human capital must be made rather early in life, they tend to subject the donor generation to capital market constraints. Yet, from the point of view of the recipients, human capital inheritances are effectively received late in life because they manifest themselves in steeply-rising age-earnings profiles. Thus the recipients become subject to borrowing limitations as well. By contrast, persons less well-endowed with human capital typically have flat age-earnings profiles. In this respect, then, the upper (labor) income groups are more likely to be reactors than planners. At least where young families are concerned, redistribution from poor to rich may well increase total spending!

### *B. Social Security as an Example*

The Social Security System is probably the biggest program of intergenerational financial transfers in our society, and it illustrates the usefulness of both the life-cycle perspective and the planner-reactor dichotomy. Without taking the life-cycle point of view, one might expect such a program of forced saving to reduce voluntary private saving roughly dollar for dollar. Yet the data seem to refute this.

Martin Feldstein and Alicia Munnell used the life-cycle model to provide one plausible explanation for this "paradox": if the social security system induces earlier retirement, more intra-life-cycle savings will be needed to finance the longer retirement periods. Here is another, applicable

[4] There are other determinants of which households are constrained, such as unanticipated spells of unemployment, but these are beyond the purview of this paper.

in the case of planners. Increases in social security benefits are generally not fully funded. Planners thus correctly perceive increases in social security as *negative bequests*, that is, as forced transfers from their children to them. As Gary Becker and Robert Barro have pointed out, the rational response is to increase their previously planned bequests so as to compensate their children for the government's action. To do this, they will save more.

If social security induces more workers to retire abruptly at age 65, as Feldstein and Munnell suggest, then optimal consumption theory provides still another explanation for the paradox. Since leisure time and consumption are presumably complementary, the abrupt upward movement in leisure time at retirement will make a corresponding abrupt upward movement in consumer spending optimal. This means "tilting" the lifetime consumption path towards lower consumption, i.e., higher savings, in the preretirement years.[5]

For reactors, there is an entirely different reason to expect increased levels of social security benefits and taxes to induce greater private saving. Nonfunded social security benefits raise life resources and thus desired consumption, while higher payroll taxes reduce current take-home pay. This forces households constrained by borrowing limits to curtail consumption. Note also that by transforming some households from planners to reactors, social security increases the income-sensitivity of the aggregate consumption function.

## II. The Wealth Elasticity of Bequests

As the size and timing of bequests are such crucial determinants of life cycle saving behavior, it is worth pausing to inquire into the motives for bequests, the form of bequests, and how the optimal bequest varies with wealth.

### *A. Motives for Bequests*

The conventional approach is to consider the bequest—or, what amounts to approximately the same thing, the wealth or utility of the beneficiaries—as another argument of the utility function. This hypothesis has a certain intuitive appeal, and may be descriptively accurate Equally important, economists have been developing the utility-maximization model for 100 years and by now can do quite a lot with it.

Becker's model of intergenerational transfers is a case in point. By some reasonable-sounding assumptions, Becker is able to demonstrate that the wealth elasticity of bequests must exceed unity—an empirical proposition which, if true, has some very fundamental consequences (see below). His argument can be paraphrased as follows. Suppose that the current family head acts *as if* he were maximizing a homothetic utility function with the wealths of the current and all future generations as arguments, and that capital markets are sufficiently perfect to permit him to do this. Then he will want to spread any increment to his own wealth proportionately over all generations. This means that he will consume only a small fraction of any marginal addition to wealth, bequeathing the rest. Since bequests are a small fraction of wealth, the *percentage* rise in bequests will be very large.

Becker's assumptions are less innocuous than they seem. Suppose instead that people only allocate *their own* life resources and that the utility function is not necessarily homothetic. The following function is sufficiently general to illustrate the point:

$$U = \frac{C^{1-\delta}}{1-\delta} + \phi\frac{B^{1-\beta}}{1-\beta},$$

where $C$ is own consumption and $B$ is the

[5] If $U(C,L)$ is the utility function, where $C$ is consumption and $L$ is leisure time, then $U_C(C,L)$ is a continuous function of time along an optimal path. Assuming $U_{CL}(\cdot) > 0$ and $U_{CC}(\cdot) < 0$, a discontinuous upward increment in $L$ necessitates a discontinuous upward movement in $C$.

bequest. Indifference curves are homothetic if and only if $\delta=\beta$, and in this case the wealth elasticity of bequests is unity. If, $\delta>\beta$ instead, the wealth elasticity of bequests exceeds one, and if $\delta<\beta$, the wealth elasticity is less than one.[6]

Hal Varian has suggested a different motive for bequests: that parents bequeath wealth to ensure that their offspring do not wind up too low in the income distribution. There is no obvious implication about the wealth elasticity of bequests, but the notion does imply that the average level of bequests increases with increasing inequality.

No mention has been made thus far of the number of children. Both of the aforementioned motives, and most others, suggest that the taste for bequests—the parameter $\phi$ in the utility function—would rise with the number of children. If this is the case, a slower population growth rate will lead to lower levels of bequests. However, with fewer human beings in which to invest, the composition of intergenerational transfers should shift more from human form to financial form, so financial bequests may not fall.

*B. Bequests in Human or Financial Form?*

Whether human or financial wealth is the medium for intergenerational transfers is important for macroeconomic reasons largely because bequests in human form usually entail either consumer expenditures in the national income accounting (*NIA*) sense, or withdrawals from the labor force, whereas financial bequests constitute *NIA* savings. Furthermore, discussion of the form in which bequests are left sheds insight on the wealth elasticity. This is because a compelling theoretical argument can be made that marginal adjustments in lifetime savings (i.e., bequests) will be made preponderantly in financial form by the wealthy and in human form by the not-so-wealthy.

The argument, which is developed formally by T. Ishikawa (1975) and Donald Parsons, is simple and intuitively appealing. Due to the finite capacity of human beings, bequests in human form are subject to the law of diminishing returns in that successive increments of financial sacrifice by the parents lead to smaller and smaller financial gains for the children. Bequests in financial form, by definition, cannot be subject to such diminishing returns.[7] Optimal behavior, then, will lead decedents to make all bequests in human form until the rate of return on human capital is reduced to the opportunity cost of funds, and thereafter to make all bequests in financial form. This is illustrated in Figure 1, Panel (a), where H* is the critical level of human wealth.

Apparently, most families do not reach H*, for such data as exist show that very few bequests are made in financial form. In a 1959 survey, 73 per cent of all household heads aged 55–64 reported receiving no inheritance, and only about 2 per cent reported receiving $25,000 or more. The average reported financial inheritance, $2,800 per household, must have been dwarfed by the typical human inheritance.[8]

Suppose we had data on bequests, and their division between human and nonhuman form, for a cross-section of families. What would we see? Since, the point H* varies among families because of differing discount rates, genetic endowments of human capital, numbers of children, and other things, we might observe smoothly concave and convex functions for human and financial bequests respectively, as shown in Panel (b). In a word, the elasticity of financial bequests with respect to

[6] For a proof, see the author (1974), pp. 35–37.

[7] Both, of course, may be subject to the law of diminishing marginal utility.

[8] I made these computations from the original data tape collected for the study by James Morgan et al.

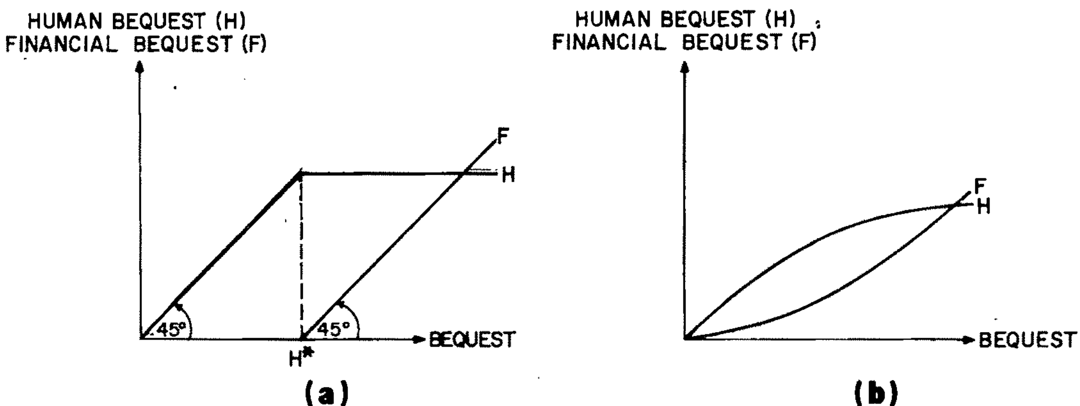

FIGURE 1

total bequests would exceed unity, so the wealth elasticity of financial bequests would exceed the wealth elasticity of total bequests. This is an important point since all efforts to measure the wealth elasticity of bequests (see below) have focused on financial bequests.

Perhaps offsetting this tendency in the upper income strata is the differential tax treatment of human and financial bequests. Intergenerational transfers of human capital are generally not taxed, and often are subsidized. By contrast, financial bequests above $60,000 are subject to a progressive Federal estate tax, and most states levy progressive inheritance taxes as well. Because of this progressivity, post-tax estates could be a concave function of lifetime wealth even if pre-tax bequests are a convex function. A descriptive regression fitted to grouped data on 1969 Federal estate tax returns is:

$$\log(\text{estate tax}) = -5.226 + 1.259 \log(\text{economic estate} - \$60{,}000)$$
$$(.308) \quad (.025)$$
$$R^2 = .995, \qquad \text{standard error} = .222,$$

which indicates substantial progressivity in marginal, as well as average, tax rates. However, this ignores the fact that accrued capital gains bequeathed at death escape taxation entirely.

Finally, note that the conclusion holds only for cross-section comparisons, not for time series trends. Schooling is a labor-intensive activity in which productivity gains are likely to be minimal. So the cost in dollars of purchasing the number of years of schooling represented by point H* in Figure 1 rises roughly at the same rate as per capita income.

### *C. Guesstimates of the Wealth Elasticity of Bequests*

Whether the wealth elasticity of bequests exceeds or falls short of unity governs whether the lifetime *MPC* falls or rises as we move up the income scale. This, in turn, has a number of important macroeconomic implications. Suppose, for concreteness, that the wealth elasticity of *financial* bequests is greater than one. Then a permanent equalization of the income distribution will permanently raise aggregate consumption. Also, since the savings rate will rise as per-capita wealth increases, a growing economy will have a rising capital-output ratio. If the aggregate elasticity of substitution is less than one, labor's share in national income will be steadily increasing. Each of these tendencies is reversed if the wealth elasticity of bequests turns out to be less than unity.

Of course, these tendencies are derived from the behavior of *inter*-life-cycle sav-

ings, which are likely to be dwarfed by *intra*-life-cycle savings if the population is growing rapidly. But if the brave new world of the future does indeed have zero population growth, these trends, which have been masked so long, will begin to come to the fore.

To date, lack of either time series or cross-section data on lifetime income and bequests has precluded direct measurement of the wealth elasticity of bequests. However, several indirect—and highly questionable—attempts have been made to estimate it.

One indirect way is to look for systematic differences in marginal propensities to consume *permanent income* by income class, as I did in my 1975 paper. I found that aggregate time series data for the United States since World War II have little power to discriminate among competing hypotheses. Such evidence as I did turn up consistently pointed to a wealth elasticity of bequests below unity; but I am not convinced. Real-world shifts in the income distribution confound transfers between rich and poor with transfers between young and old, male and female, black and white. Further, for reasons cited above, the rich may be reactors more frequently than planners. If so, their high *short-run MPC*s could be incorrectly labelled as high *long-run MPC*s, given the imperfect nature of the distributed-lag proxy for permanent income.

Using cross-section data by state, Hal Varian regresses the average bequest in the state ($b_i$) on average lifetime income in the state ($y_i$), income squared, and the interaction of income with a measure of income inequality ($P_i$, for the Pareto measure). This seemingly direct measurement also constitutes an indirect test because, except for the inequality measure, *none* of the data needed for Varian's study exist! His technique might well be called "regression without data." Varian uses *annual* income in the state as a proxy for *lifetime* income, and fabricates data for $b_i$ by the clever, but probably dubious, assumption that the average level of bequests among estates below $60,000 is the same in each state. He finds a negative coefficient on $y^2$, suggesting a concave $b(y)$ function, which is consistent with my findings. However, the negative coefficient on $P \cdot y$, which he interprets as support for his hypothesis,[9] would also be interpreted as evidence for a convex $b(y)$ function.

Finally, in a current Ph.D. dissertation, James Adams tries to estimate the wealth elasticity of bequests in a cross-section of individuals by using current net worth as a proxy for bequests and current earnings as a proxy for lifetime income. Given that both lefthand and righthand variables are proxies, it is hard to interpret his finding of an elasticity well in excess of unity. For example, it may just reflect the high elasticity of asset-holding with respect to earnings *within* the life cycle, despite his attempt to devise a statistical control for age.

### III. Concluding Remark

It is typically the case in economics that theory is needed to unearth the interesting questions, while empirical research is needed to answer them. So it is here. Despite some crude attempts using aggregate time series, a cross-section of states, and a cross-section of individuals, it must be admitted that we know relatively little about the wealth elasticity of bequests. In the case of capital market imperfections, the theoretical notions have yet to be given empirical substance. Twenty years after the seminal contributions of Modigliani and Friedman, the aggregate consumption function retains some of its mystery.

[9] The Pareto coefficient declines as inequality rises.

# The Optimal Taxation of Commodities and Income

*By* DAVID F. BRADFORD AND HARVEY S. ROSEN*

The last few years have seen a resurgence of interest in the old question of how best to raise tax revenue. Roughly speaking, two different problems have been studied. The first is to find a set of commodity taxes that is optimal given certain efficiency and (sometimes) equity considerations. In a second strain of the literature, it is assumed that the revenue system is based upon income rather than commodity taxation, and the problem is to determine the optimal degree of progressivity (or regressivity).[1,2]

The principal motivation of some writers in the optimal taxation literature seems to be the discovery of fairly simple rules which policy makers actually can implement. Others are more interested in theoretical exploration of the implications of alternative economic assumptions than in developing usable policy recommendations. Practically all the contributions, however, have been quite mathematical and thus inaccessible to many practitioners in the public finance area. The purpose of this essay is to discuss in a nontechnical way the methodology and principal conclusions of the optimal taxation literature.[3]

In Sections I and II are discussed the optimal commodity and income tax literatures, respectively. Following this are some observations on the accomplishments of optimal taxation research and on some open questions.

## I. Optimal Commodity Taxation

Since the literature contains many and varied derivations of the principal theorems of optimal commodity taxation,[4] we shall not carry out detailed proofs here. We can point out, however, some of the variations in the way the problem is posed. Most commonly a revenue constraint is taken as a starting point, together with an assumption that the government must use per unit commodity taxes. Thus lump sum taxes are excluded. If $x_i$ is the quantity of the $i$th good purchased by the household sector from the production sector (negative if the households are net sellers, as in the case of the commodity "leisure"), and $T_i$ is the per unit tax, the revenue constraint is

$$(1) \qquad \sum T_i x_i = R,$$

where $R$ is the required revenue level.

The taxes are the difference between the

* U.S. Treasury Dept. and Princeton University, respectively. The authors would like to thank Roger Gordon for useful conversations and Jay Stuart for assistance in gathering material. An extended version of this paper is available upon request to the authors.

[1] There is some overlapping of these strains. For example, A. B. Atkinson and Joseph E. Stiglitz consider the problem of differential commodity taxation in the presence of an income tax.

[2] Although we shall focus upon these problems in this paper, the optimal tax literature has had a somewhat wider scope. For example, Peter A. Diamond and James A. Mirrlees consider the problem of optimal expenditure along with taxation.

[3] Consult Nicholas Stern or Atkinson and Stiglitz for more technical surveys.

[4] See, for example, Frank A. Ramsey, M. Boiteux, or Agnar Sandmo.

prices, $p_i$, received by producers and $P_i$, paid by the consumers,

$$T_i = P_i - p_i. \tag{2}$$

It is frequently assumed that producer prices are fixed, so that by setting taxes we set consumer prices and hence consumer welfare. The problem is then to make the choice of taxes in such a way as to maximize the resulting consumer welfare, i.e., to minimize excess burden.

A typical approach is to assume there to be only one consumer (hence no distribution problem), with a utility function $U(\cdot)$ depending on consumption vector $x$. Thus the objective might be to choose $P$ (a vector of consumer prices) and $p$ (a vector of producer prices) to

$$\text{Maximize } U(x(P)) \tag{3}$$

subject to

$$\sum_i x_i(P)P_i = 0^5$$

and to

$$U_i(x(P)) = aP_i. \tag{4}$$

Conditions (4) are the familiar first order implications of the household's optimization, with $a$ being the Lagrangian multiplier.

More often an indirect utility function $V(P, 0) = U(x(P))$ is used, (the zero argument draws attention to the assumption of no transfer income) because the derivations become very simple when use is made of "Roy's Identity"

$$\frac{\partial V}{\partial P_i} = -x_i(P)\cdot\frac{\partial V}{\partial M}, \tag{5}$$

where $\partial V/\partial M$ is the "income" derivative.

Putting these pieces together in any of several sequences leads to the famous Ramsey result on optimal commodity taxation:

$$\sum_i T_i S_{ik} = bx_k, \qquad k = 1, \ldots, m \tag{6}$$

where $S_{ik}$ is the derivative of the demand for the $i$th good with respect to the $k$th price, other prices and utility being held constant, and $b$ is independent of $k$. The lefthand side gives an estimate of the change in demand for the $k$th good which would occur if the taxes were removed. Hence (6) says that the proportional change in demand (thus estimated) should be the same for all commodities—the Ramsey result.

Conditions (6) can also be expressed in terms of elasticities. Probably the most familiar "optimal tax" result is the form which applies when the off-diagonal elasticities are zero. In this case the first order conditions associated with (3) lead to the "inverse elasticity rule":

$$t_r = \frac{d}{E_{rr}}, \qquad r = 1, \ldots, m. \tag{7}$$

where $t_r = T_r/P_r$, the percentage or ad valorem rate of tax, $d$ is a constant, and $E_{rr}$ is the elasticity of the ordinary (uncompensated) demand function for the $k$th good. This formula has certainly been of importance in forming economists' intuitions on tax and price regulatory questions. It underlies the notion of charging according to "what the traffic can bear" in transportation, for example, and is the basis for the acceptance on efficiency grounds of such taxes as those on tobacco and alcohol, the demand for which is presumed price inelastic.

An important application of the analysis is to the presumptive case for direct over indirect taxation. The classic Hotelling argument for marginal cost pricing seemed to some to support the conclusion that an "income tax" will involve no efficiency

[5] Paul A. Samuelson uses a somewhat different formulation of the problem and one which has the virtue of emphasizing the resource releasing function of the taxes.

cost. When it was recognized, however, that the "income" of the tax system is not the "budget level" of the elementary theory of consumer demand, but rather the product of a certain price, the wage, and a demanded quantity (negative net purchase of leisure), the apparent a priori advantage of an income tax was lost. The analyses of W. J. Corlett and D. C. Hague, I. M. D. Little and Milton Friedman to this effect all are applications of the theory of optimal commodity taxation as is neatly shown by Sandmo.

While the extensive subsequent work has shown how difficult it is to sustain *any* simple rules for commodity taxation, the result of the spreading awareness of this work has been to make economists think about tax questions in a new way and to hasten the search for rules which are reasonably robust.

For example, as Stiglitz and Atkinson point out, optimal tax analysis makes it clear that there is no a priori assurance that the income tax is the single best instrument for income redistribution—such "commodity taxes" as are represented by housing subsidies or food stamps might contribute to an optimal program. Michael Boskin notes that, in view of the differences in the observed elasticities of household supply of the two types of labor (husband labor and wife labor), it is probably efficient to tax these "commodities at different rates. Martin Feldstein (1975) uses the same basic approach to examine the choice between "tax expenditures" and direct expenditure methods of achieving an increase in a specified activity.

A natural question in view of the interpretation of the income tax as a commodity tax is whether taxation of labor only (i.e., uniform taxation of commodities) is appropriate. Not surprisingly, the answer is that it will be so when labor is inelastically supplied. Sandmo shows that this in turn will follow if utility is separable between leisure and all other goods and homogenous in those goods. Intuitively this separability means that further efficiency cannot be gained by differential taxation of goods that are "related" to leisure. Several writers have noted an important consequence when this result is reinterpreted in an intertemporal context. If utility is a function of consumption and leisure at different dates and separability obtains, then no taxes on interest income should be levied—consumption is the appropriate tax base. This simply illustrates the challenge, implicit in the optimal tax approach, to the widespread acceptance of taxation on the basis of Haig-Simons income which has been emphasized by Feldstein (forthcoming).

While an "income tax" can be regarded as a tax on the sale of labor (negative net purchase of leisure), there is a feature of actual income taxes which is slighted by such a point of view: it is institutionally feasible to assess taxes at different *rates* on different individuals; in particular, progressive taxation of earnings is possible. This means that the income tax and such related taxes as the expenditure tax are potentially important instruments for meeting distributional objectives. We now turn to the studies which consider the trade-off between such distributional objectives and economic efficiency.

## II. The Optimal Income Tax Literature

The problem of optimal income taxation has a long history in economics.[6] However, most of the recent literature stems from a paper published by James Mirrlees in 1971 A natural way to organize our discussion, then, is to summarize Mirrlees techniques and conclusions, and then view the ensuing literature as an attempt to explain and modify some of his results.

In Mirrlees' model, society is composed

[6] See especially F. Y. Edgeworth's important contribution.

of individuals who have identical atemporal utility functions in after tax income and leisure. Individuals differ only in their earning abilities (wage per hour). The government must collect an exogenously determined amount of tax revenue. The problem is to find an income tax schedule (tax function) which maximizes the sum of individuals' utilities subject to this revenue constraint.

Using the tools of the calculus of variations to solve the constrained maximization problem, Mirrlees finds that the optimal tax function exhibits marginal tax rates between zero and one, and that when it is operative, part of the population does not work. Although these results may seem weak, they are really quite remarkable given the absence of specific functional forms for the key relationships in the problem.

In order to get more specific results, more specific assumptions must be built into the analysis. Mirrlees assumes that the utility functions are Cobb-Douglas, and considers both log normal and Pareto distributions of earnings abilities. With these assumptions, the following results emerge: (a) the optimal tax function is approximately linear with a negative intercept, and (b) the optimal tax function is characterized by "low" marginal tax rates which *fall* somewhat with income. Atkinson's (1973) interpolations of Mirrlees' results indicate rates in the neighborhood of 20 percent.

Mirrlees was surprised at how low the marginal tax rates were: " . . . I must confess that I had expected the rigorous analysis of income-taxation in the utilitarian manner to provide an argument for high tax rates. It has not done so." (A study by Ray C. Fair in the same year also generated fairly low implied marginal tax rates.) Apparently, those who read the Mirrlees paper also found the low marginal tax rates counterintuitive, for much of the literature appears to be an attempt to explain them.

One concern was the maximand of Mirrlees' problem, an unweighted sum of individual utilities, which implies that a "util" to a rich individual adds as much to social welfare as a "util" to a poor individual. To what extent would more egalitarian results (i.e., higher marginal tax rates) emerge if a social welfare function were used which weighted the utilities of the rich less than those of the poor? Atkinson and Feldstein (1973) consider social welfare functions of the form

$$W = \left(\sum U_i^v\right)^{1/v} \qquad v \leq 1. \tag{8}$$

Clearly, when $v=1$, welfare ($W$) is the simple sum of utilities ($U_i$). When $v$ is less than 1, however, it can be shown that a given increment to the utility of a low utility individual adds more to $W$ than if awarded to a high utility individual. It should be noted, however, that the specifications of the social welfare function and the individual utility functions are not really independent of each other. We could, for example, specify the utility of the $i$th individual to be $U_i^v$ and then write social welfare as the arithmetic sum of these utilities.

Atkinson focuses attention on the case in which $v$ approaches minus infinity. Under such circumstances, it can be shown that maximizing $W$ is equivalent to maximizing the utility of the worst off individual in society: the maximin case. This case has received considerable attention due to philosopher John Rawls' argument that it is particularly compelling as an ethical criterion. (A number of criticisms of Rawls' position are suggested by Alvin K. Klevorik.)

Atkinson uses a Rawlsian social welfare function in a model with a linear income tax, no net government revenue requirement (i.e., taxation for redistribution

only), and a Pareto distribution of skills in the economy. He finds that optimal marginal tax rates range between 30 and 45 percent. Thus, one solution to the mystery of Mirrlees' low marginal tax rates is his formulation of the objectives of the government. Social welfare functions which are more egalitarian than the classical utilitarian variety may yield higher marginal rates.

Another potential explanation for Mirrlees' results is the Cobb-Douglas assumption on the form of individuals' utility functions. Stern has investigated this possibility by assuming that individuals have constant elasticity of substitution (*CES*) utility functions in leisure and income. Using results on the elasticity of labor supply from the econometric literature,[7] he finds that an elasticity of substitution of about .4 is more realistic than 1.0.[8] When a variant of Mirrlees' problem is solved using *CES* utility functions with this lower elasticity of substitution, the optimal marginal tax rates are substantially higher—without appeal to a more egalitarian social welfare function.

Reexamination of the social welfare function suggests another possible explanation for the low tax rates typically generated by optimal income tax studies. Our intuition about optimal income taxation may perhaps be conditioned on societal objective functions which are not utilitarian-individualistic. For example, the presence in the social welfare function of a variable parameterizing the "aesthetics" of the income distribution would lead to more egalitarian results.[9] Similarly Feldstein (forthcoming) has shown that if interdependent utility functions are allowed for, very high marginal tax rates may be appropriate.

We now turn to a limitation of the Mirrlees model which is just beginning to receive attention, its atemporal setting. The appropriate taxation of capital income is one of the most controversial aspects of the tax system, yet the studies cited above for the most part ignore it. Janusz A. Ordover and Edmund S. Phelps examine the optimal mix of taxes on two factors of production (capital and labor) in a one sector neoclassical growth model.[10] Their model is very general, and therefore no results on tax rates emerge which can be compared to those discussed above. Moreover, the only social welfare function they consider is the maximin case. Despite these limitations, explicit attention to the taxation of capital income in the optimal income tax framework is an important step which will no doubt stimulate further research.

We could continue to list additional aspects of the Mirrlees model which have been changed and expanded in order to ascertain their effects on optimal tax rates.[11] However, the basic thrust of the literature should now be clear. An exogenously determined amount of tax revenue must be raised by income taxes on individuals whose economic choices are distorted by the presence of those taxes. Given technological and behavioral assumptions, the optimal tax schedule is that which leaves some social welfare function at a maximum after the tax is collected. The literature shows how various

[7] These are measures of the elasticity of hours per year with respect to the wage, and thus do not take into account other, perhaps more important, dimensions of labor supply.

[8] If the elasticity of substitution were zero, lump sum taxation would be possible. If the elasticity of substitution were infinite, no revenue could be raised.

[9] Such a social welfare would be non-Paretian, but there is nothing to prevent a reasonable set of value judgments from allowing for such a possibility.

[10] E. Sheshinski (forthcoming a) considers taxation in a one sector neoclassical growth model with earned and unearned income taxed at the same rate.

[11] For example, Stern has suggested changing the assumptions on the underlying distribution of skills, Sheshinski (forthcoming b) focuses attention on a model in which taxes influence human capital accumulation, and Feldstein (1973) allows for an endogenous wage.

assumptions on these components lead to different conclusions regarding the shape of the optimal income tax schedule.

### III. Concluding Remarks

The accomplishments of the optimal taxation research have been considerable. It has upset many comfortable rules of thumb and lent precision to many informal arguments. But there remains work to be done. Part of this work will, of course, consist of increasing the stock of variations on the basic problems for which solutions have been described. Another, and very important part will consist of the attempt to determine quantitatively which of these problems best describes the actual economy to be taxed—filling in all those empty boxes with real, estimated elasticities.

However, work of another kind is needed to advance the normative power of the analysis. Normatively the optimal tax literature rests on a utilitarian base. It is true that the optimal commodity tax results, or some of them at least, can be cast, in a form which says: if your tax system doesn't look like this, there is a potential bargain which can be struck among your citizens which would make all better off. However, these bargains are complex and their possibility tends to be eliminated by the very assumptions that require the use of second-best instruments in the first place. For practical application implicit interpersonal utility comparisons are required. The optimal income tax results are also dependent on such comparisons. The missing link is a welfare function, and the question is how does one persuade a legislature or an electorate to decide in accordance with some particular welfare function?

Asking the optimal tax researchers to resolve this is effectively to ask them to make welfare economics persuasive, obviously a tall order. But, interestingly, the tax literature has always appealed to non-utilitarian criteria as well.

Thus, missing from the optimal tax literature is the idea of horizontal equity, the notion that " . . . people in equal positions should be treated equally." (Richard A. Musgrave 1959, p. 160) (Customarily, "equal positions" are defined in terms of an observable index of ability to pay such as income, expenditure, or wealth.) In none of the studies discussed above has the injunction to treat equals the same appeared either as a constraint in the maximization problem, or as an argument in the objective function. Therefore, they will in general[12] fail to provide horizontal equity. In light of this, Musgrave (forthcoming) and others have suggested that it is inappropriate to characterize such schemes as "optimal."

Defining horizontal equity in terms of income is inadequate because individuals with identical opportunity sets but different tastes will have different incomes. An alternative way to define equal position would be identical opportunity sets. However, it seems more in the spirit of the optimal taxation literature to define equal position in terms of utilities: individuals are "the same" only if they derive identical amounts of utility from their consumption and leisure bundles. The choice of a criterion for horizontal equity is important because when tastes differ between individuals, different criteria may lead to different conclusions as to the fairness of a given tax. For example, an income tax which is perfectly fair according to conventional notions of horizontal equity hurts an "income lover" more than a "leisure lover."

In an attempt to put the discussion of

[12] It can be shown that if all individuals have identical tastes and there is only one type of ability, then horizontal equity will be satisfied by virtually any broad-based tax. (See Feldstein, forthcoming.) Such assumptions, as we have seen, are built into a number of the optimal tax studies. For an exception, see Diamond and Mirrlees.

horizontal equity and the optimal taxation literature on the same plane, Feldstein (forthcoming) has redefined the principle of horizontal equity in terms of utility rather than ability to pay.[13] However, complete integration of horizontal equity into the optimal tax framework remains to be done. Perhaps this could be accomplished by including some measure of departure from horizontal equity as an argument in the social welfare function, but this approach is bedeviled by conceptual difficulties in measuring departures from horizontal equity.[14]

It may well be that horizontal equity, ancient and honorable criterion of tax policy though it be, is not a helpful concept. However, apparent appeal of this nonoperational idea to practical people suggests the attractiveness of properties of a tax structure which are independent of the economy to which that structure is applied. To discover whether there are any such properties which significantly narrow the range of "good" tax structures might be a useful topic of research.

[13] "If two individuals would be equally well off (have the same utility level) in the absence of taxation, they should be equally well off if there is a tax."

[14] See Rosen for a discussion of these problems and some attempts to surmount them.

# On Some Recent Econometric Research in Public Finance

By Michael J. Boskin*

In a field like public finance which is intimately concerned with the formulation and evaluation of public policy, the continuing search for scientific information (upon which to base such policies) acquires a particularly large marginal social product. Yet, throughout the history of public finance there has been at times a harmonious blend of the analytical with the empirical and at other times a flagrant clash between them. From such clashes a synthesis frequently has been developed which gains widespread acceptance. The point is simply that scientific information is only acquired as the intersection of theoretical and empirical research. Once this is recognized, there are three basic ways in which we are able to improve our basic knowledge: we may develop new and better theoretical insights; we may obtain more data, or improved data, or both; and we may develop superior methods by which to analyze data.

In the last few years, a number of excellent examples of each type of progress in public finance have been produced. The purpose of the present paper is to discuss several examples of recent econometric work in order to indicate the enormous progress that has been made in obtaining vastly improved estimates of some of the key parameters with which we are concerned. In so doing, we shall also note how these empirical findings sometimes force us to abandon previously held beliefs and ways of thinking about certain problems.

Toward this end, Section I discusses some recent evidence on the effect of the charitable contributions deduction on giving to charity. This recent work is based on a variety of data sources and employs some relatively advanced econometric techniques to estimate the price and income elasticities of charitable giving. The estimated price elasticities are much larger than those which had been accepted previously and have strikingly different implications for public policy. Thus a reworking of what is basically a simple problem of estimating the demand for a single commodity has resulted in an enormous advance. Section II deals with recent advances in the analysis of the effects of taxes on the supply of labor. I include this topic both to illustrate my major point in an area of incredibly rapid technical progress and to demonstrate how public financiers also must rely on research from related fields. The conceptual and estimation problems in this area are much more complex than those for the analysis of tax incentives for charitable giving, but we are converging (slowly) on a better understanding of the ways in which taxes affect labor supply.

Section III reports on some recent research on the effects of taxes on saving behavior. Again, more and better data and advances in econometric techniques have led to empirical results which are forcing

* Stanford University and the National Bureau of Economic Research. This paper is part of a planned larger survey of empirical research in public finance. It is meant to illustrate the types of progress being made, not to survey the field comprehensively. Indeed, anything approaching a complete list of references would probably exceed my modest page limit! See G. F. Break (1974) for a partial survey.

us to rethink some widely accepted propositions on the incidence and effects of taxation. Here the focus is on simple macroeconomic models and different types of data and estimation problems than in the examples cited above.

Finally, Section IV offers a brief summary and suggestions for future research.

## I. The Effects of Tax Incentives on Giving to Charity

As an example of a wide range of problems in the analysis of the effects of tax deductibility of any particular item, consider the deductibility of charitable contributions in the income and estate taxes. For those persons itemizing deductions, deductibility lowers the cost of giving to $1 - r$, where $r$ is the marginal tax rate. A frequently used measure of the efficiency of a tax deduction is the ratio of the induced increase in a particular activity (such as charitable giving) due to the deduction, to the revenue foregone by the Treasury. Obviously, this ratio is a key parameter in policy discussion and its size is a function of the price elasticity of demand for the commodity under consideration.

Until quite recently, it was thought that the charitable deduction had very little impact on giving. For example, William Vickrey (1962) concludes that ". . . the evidence would seem to indicate that while the deductibility may increase the gross amount of contributions, it does so by less than the tax relief granted." Further, Michael Taussig (1967) estimated that charities received only five cents for every dollar of revenue foregone by the Treasury. Unfortunately, Vickrey does not estimate a demand for giving equation and Taussig does so in a way that obscures the relationship between giving and after-tax cost.[1] Thus, their conclusions are not the sort of information upon which one would want to base tax policy toward charitable contributions.

In somewhat of a tour de force, Feldstein (1975a,b) and Feldstein and his collaborators (1975a,b, 1976) have examined several complementary data sources and estimated demand for charitable giving equations. The basic equation estimated in each of these studies is of the form

$$ln\ G_i = \alpha_0 + \alpha_1\ ln\ Y_i + \alpha_2\ ln\ P_i + \epsilon_i$$

where $G$ is charitable contributions, $Y$ is income and $P$ is net-of-tax price. The results indicated a price elasticity in excess of unity in virtually every case. Note that this result suggests that charitable organizations gain absolutely *more* than the Treasury loses in revenue, i.e., the deduction is more than fully efficient. Feldstein (1975a) also notes that eliminating the deduction would increase inequality in the after tax and giving distribution of income.

The most important thing to note about this work from a methodological point of view is the bringing to bear of a variety of different data sources to attempt to answer the same question: How large is the price elasticity of giving to charity? Feldstein and his collaborators use pooled aggregate statistics of income data by income class, individual tax return data from 1962 and 1970 tax returns and household survey data. Thus the advantages of several types of data have been exploited. For example, the household survey data include much information on demographic variables which influence charitable giving and these have been used as additional regressors in the basic equation; the pooled time series data are useful in dealing with the permanent-transitory income problem, etc.

Contrast this approach of examining several data sources in analyzing a particular problem with the typical approach in

[1] See Martin Feldstein, 1975a.

empirical work in public finance (and other fields of economics). Usually, we witness a sporadic series of difficult to compare studies produced over a long period of time using different data sources, econometric techniques and definitions of variables. Then someone writes a survey paper bemoaning the differences in the studies and heroically attempting to determine if the difference is due to the different data sources, the different techniques used to analyze the data or some change over time or across demographic groups in the underlying behavior. The policy maker frequently is left to choose from a bewildering array of conflicting studies.

While applying the same techniques to a variety of types of data sources will not always lead to virtually identical results, it frequently will be the case that knowledge of the advantages and limitations of the alternative data sources can be combined with econometric techniques to narrow substantially the confidence intervals we attach to estimates of key parameters.

A second major methodological feature of these studies is the attempt to examine a variety of functional forms, definitions of the variables and subsamples of the population in order to test the robustness of the basic results. For example, in addition to the basic constant elasticity demand equation described above, Feldstein et al. estimated equations in which the price elasticity was allowed to vary with price and the income elasticity with income; in which separate price elasticities were estimated for separate income classes and age and marital status groups; and in which alternative reasonable measures of price and income were used. Fortunately, the results supported the basic conclusion of a greater than unitary price elasticity.

Economic theory *generally* guides us to a set of structural relationships to study; it *sometimes* places meaningful restrictions on some of these relationships (nonnegativity, symmetry, etc.); however, it *rarely* implies a precise functional form. Further, the available data usually do not contain information which enables us to conform exactly to our theoretical definitions of variables. Hence, it is important to explore the robustness of our results to alternative specifications. Combined with an analysis of alternative data sources, this approach in at least a subset of cases will lead to results which may be imbedded in the subsequent analysis and discussion of the problem under investigation. For example, the results of Feldstein et al. have replaced the earlier results and the simple cross-tabulations from tax data which have ignored these behavioral responses.

We shall see below that studies of the effects of taxes on labor supply suffer in the extreme from noncomparability of data source, estimation technique, functional form and variable measurement, whereas studies of saving behavior partly follow the pattern outlined above. Before turning to these studies, however, it is worth noting one more type of advance that has been made in the recent literature on taxes and charitable contributions.

A variety of recently developed econometric techniques are continually in the process of diffusion throughout the profession. One type which is becoming increasingly important in public finance and other fields which analyze data on individual households is the analysis of qualitative and limited dependent variables. These techniques are designed to deal with situations where the dependent variable in a relationship must take on one of a mutually exclusive set of discrete values or piles up at some limit. For example, a person chooses whether or not to be in the labor force, which college to attend, which transport mode to take to work, etc. In the an-

alysis of data on charitable bequests, one is confronted with precisely such a problem. Only twenty percent of decedents leave anything to charity. Hence, in regressions such as those described above for charitable contributions under the income tax, of charitable bequests on wealth and price, eighty percent of the observations on the dependent variable are zeroes! Fortunately, techniques have been —and are being—developed to handle these problems. As an example of the potential difficulties involved, Stephen K. McNees (1973) estimated such an equation using ordinary least squares. His results predict that most estates bequeath negative amounts to charity.[2] I have reestimated his equations using the truncated normal regression model and have estimated substantial price elasticities of charitable bequests. We shall return to a discussion of these techniques below.

## II. The Effects of Taxes on the Supply of Labor

The importance of estimates of the effects of taxes on the supply of labor to the making of intelligent tax policy is difficult to overemphasize. Answers to such structural questions as an appropriate unit of account for taxation and to such fundamental issues such as the optimal progressivity of the income tax depend crucially upon the effects of taxes on labor supply. Indeed, much recent theoretical and empirical research in public finance focuses on relaxing the assumption of fixed factor supplies. We deal with labor and capital in turn.

The last few years have witnessed an explosion of research on labor supply. It illustrates two other crucial types of (admittedly sporadic) progress being made in econometric research in public finance: the availability of new bodies of data potentially useful in the study of a wide variety of problems and major advances in econometric technique. New and important sets of data containing information on individual households have become increasingly available. This development in itself has enormous import for empirical work in public finance as it potentially frees us from exclusive reliance on time series data and its inherent problems. Examples include the 1966 and 1967 *Surveys of Economic Opportunity*, the *Panel Study of Income Dynamics*, and the *National Longitudinal Surveys*. These data allow us to follow the same households over several years; special methods for analyzing such data are now emerging. Finally, controlled social experiments are producing data which complement these other data sources in important ways.

All of these data sources have been used in attempts to estimate labor supply functions. Unfortunately, different techniques have been applied in each of these studies. For example, Boskin (1974) and Robert E. Hall (1974) use the Survey of Economic Opportunity to estimate labor supply for various groups as a function of after-tax income and wage rates. James J. Heckman (1975), using the National Longitudinal Survey, makes an important conceptual advance, but totally ignores taxes in measuring wage rates! Harvey S. Rosen (1973) reports results from this same body of data supporting the hypothesis that it is after-tax rather than gross wage rates that matter. It seems as if each paper has made an advance but generally ignores those made previously. Hence, the studies are extremely difficult to compare and no clear consensus on elasticities of labor supply has emerged. About all that can be said in surveying the studies is that the labor supply of wives seems to be more wage-elastic than that of husbands; while the latter (at least ignoring human investment on the job) appears to

[2] See Boskin, 1976.

be relatively inelastic, estimates of the former range from well under one to well over two. Worse yet, every estimate I have seen is inconsistent in the statistical sense due either to econometric technique used or to measurement of the variables.

The study of labor supply also provides an excellent example of the interaction of data availability, policy relevance and conceptual advances. There is no question that the intellectual interest (not to mention financial support) in research on labor supply was stimulated by the debate over the labor supply effects of a negative income tax. A variety of successive and important conceptual advances have been made. For example, the typical labor supply study of several years ago merely regressed hours of work on wage rates and a measure of income. For groups of the population with labor force participation rates well below 100%, this procedure is inappropriate. Further, imputing wages to those not currently working by comparison with those who are may also lead to inconsistent estimates.[3] For example, Heckman points out that if

$$W_M = f(E, S)$$

$$W_A = f(C, A, W_s, H)$$

(where $W_M$ is the market wage rate facing a potential worker, $W_A$ is the asking wage, $E$ is labor market experience, $S$ is years of schooling, $C$ is the number of children, $A$ is assets, $H$ is hours of work, and $W_S$ is spouse's wage), hours of work will adjust so that $W_A = W_M$ for workers, whereas $W_M < W_A$ if hours of work in the market are zero. He uses this simple observation to build an econometric technique for estimating these two functions, which may be solved for the market labor supply function. The technique is a generalization of the truncated regression model (usually called Tobit analysis) discussed above. It solves many of the problems encountered in the previous work on labor supply.

Unfortunately, Heckman's estimates are not yet readily usable because he ignores taxes in the measurement of wage rates; hence his estimates are inconsistent. G. Hanoch (1975), in an excellent paper, has extended the Heckman notion in a variety of ways. However, nothing like a systematic combination of the improvements in measurement, in conceptualization, and in econometric technique has been used to analyze a variety of complementary data sources. From the point of view of the consumers of estimates of the effects of taxes in labor supply, such a synthesis is badly needed and long overdue.

### III. Taxation and Saving

The recent econometric research in taxation and saving behavior has not been pushed forward primarily by new econometric techniques. Rather, it has been, marked by a more careful examination of the fundamental relationships, an attempt to incorporate potentially important missing elements and an examination of alternative data sources and functional forms. In addition to the obvious direct usefulness of this work, it is particularly important because the recent results are forcing us to reexamine widely held views on tax incidence.

The three most important lines of inquiry, in my opinion, have been the study of the relationship of corporate and personal saving, the social security system, and the interest elasticity of the saving rate and public and private marginal propensities to save.

The typical consumption or saving function related consumption or saving to private income after taxes, excluding retained earnings. Feldstein (1973) and Feldstein and G. Fane (1972) have extended this

[3] See J. Heckman, 1975.

model to include the "components" of capital gains, including retained earnings. The estimates based on *U.S.* and British time series data, respectively, suggest that the marginal propensity to consume out of retained earnings is two-thirds that out of disposable income. Again, these results are derived from a variety of specifications of the basic relationship, including alternative measures of permanent income. They suggest that consumers see through the corporate veil and (partially) adjust their personal saving to changes in corporate saving.

A second line of work, also pioneered by Feldstein (1974a, 1975d), and contributed to by Alicia H. Munnell (1974), has been the study of the effects of social security on private saving. The enormous increase in social security benefits financed on a pay-as-you go basis has been one of the most important features of the postwar *U.S.* economy. It is conceivable that the expectation of social security payments during retirement, financed by the generation then working, leads to a decrease in private saving. Feldstein has examined two different types of data to attempt to answer this question. His studies of aggregate *U.S.* time series and an international cross section imply that an enormous substitution of expected social security benefits for private saving has occurred. Indeed, his best estimates are that the substitution is virtually dollar for dollar and that the *U.S.* private saving rate has been reduced by thirty percent or more by the social security program.

Finally, Boskin (1976) has reexamined the questions of the interest elasticity of the saving rate and differential marginal propensities to save publically and privately raised by Feldstein (1974a,b), Peter A. Diamond (1970), C. Wright (1969) and Warren E. Weber (1970, 1975). Paying particularly close attention to the measurement of saving and real after-tax rates of return, he estimates an interest elasticity of approximately .4; this estimate is much larger than that found in previous work. He also concludes that the marginal propensity to save out of private after-tax income is over twice that out of government revenue.

Again, as with the study of charitable contributions, these studies are marked by an attempt to bring several data sources to bear on the same question; to examine the robustness of the conclusions to alternative sample periods, definitions of the variables, and functional forms; and to apply the most reasonable econometric techniques warranted by the problem and the data. Unlike the studies of charitable contributions, the studies of taxation and saving have implications far beyond the particular problem addressed. For example, some widely held notions on the incidence of taxation *assume* that the policies under study do not affect saving, the capital-labor ratio, and hence the functional distribution of income. Indeed, much of the profession seems to give a behavioral interpretation to what has come to be called Denison's Law.[4] The studies mentioned above call this assumption into serious question. Feldstein's estimates of the impact of the social security system on private saving indicates that the *benefits* side of social security has sharply increased the rate of interest and decreased the wage rate. My estimates of the interest elasticity of the saving rate imply that the traditional view—embodied in virtually all empirical estimates of tax incidence—that a proportional income tax is borne in proportion to income is erroneous; labor bears more than its proportion of national income. Further, taxes on capital income are largely shifted onto labor; hence, the traditional views on the inci-

[4] See P. David and J. Scadding, 1974.

dence of capital income taxes may need to be replaced.

## IV. Conclusion

I have tried to illustrate in the brief space provided me the important advances that have occurred recently in econometric work in public finance. It seems to me we have entered a new era where both the quality and quantity of econometric research are improving rapidly. As noted above, there are several reasons for this state of affairs. First, a variety of new data sources have become available. Second, new techniques for analyzing that data have been developed. Third, a style of research placing heavy emphasis on exploiting alternative data sources and examining the robustness of the results to alternative specifications has emerged.

I have no doubt that while the particular studies mentioned will be improved by still more and better data and techniques, the methodological message they impart will serve to upgrade the quality of both the future empirical research in public finance and the information upon which sound public policies ultimately must be based.

STATE AND LOCAL PUBLIC FINANCE

# Institutional Constraints and Local Community Formation

*By* RICHARD E. WAGNER*

The interest of economists in alternative patterns of urban government stems primarily from the publication of papers by Charles M. Tiebout and George J. Stigler. While these papers were essentially positive in orientation, subsequent work explored the normative properties of various models of urban government. These normative models, which have been surveyed exhaustively by Kenan Bulutoglu, have predominantly focused on the external costs that units of government impose on one another. While particular models vary, the general framework is quite uniform. A model is postulated in which the activity of one jurisdiction influences positively the utility level of residents of other jurisdictions. The analyst then postulates an "independent adjustment equilibrium," and concludes that this equilibrium is inefficient because individual jurisdictions fail to take into account the impact of their actions on other jurisdictions.

Albert Breton, Wallace E. Oates, Mancur Olson, and Gordon Tullock attributed this nonoptimality to the inappropriate specification of boundaries, for the benefit range of the publicly provided service fails to coincide with the boundary of the jurisdiction providing the service. Once it is suggested that some boundaries are better than others, the principles of community formation or boundary selection come to the fore of the economic analysis of local government. Optimality models of club or community formation have been developed by such authors as Martin C. McGuire, A. Mitchell Polinsky, and Hirofumi Shibata, these various works all being inspired by James M. Buchanan's (1965) theory of clubs.

This paper advances the thesis that the economic analysis of local government and community formation should deemphasize the construction of normative models, and should concentrate instead on the positive analysis of alternative institutional arrangements. The first section of this paper argues that the economic analysis of urban government should become less "neoclassical" and more "institutionalist" because optimality models can never be related to social reality *independently of the institutional framework within which collective choices emerge*. The second section moves beyond methodological exhortation to the description of some institutional research, with this description serving to reinforce the theme of the first section.

## I. Mind, Matter, and Institutionalist Themes

The prescriptive use of optimality models of local government requires a framework in which the analyst knows *by assumption* the mental states of the participants in the economic process. Once the essential privacy of individual minds is recognized, however, the analyst can no longer adhere to such a framework. As Friedrich A. Hayek (1937, 1945) has

* Professor of Economics, Virginia Polytechnic Institute and State University.

argued with especial clarity and force, the inherent subjectivity of the data of the models prevents an external observer from relating his conceptual constructions to reality independently of actual choices, with particular choices themselves dependent upon the constraints created by particular institutional settings.

Consider, for instance, McGuire's suggestion that institutional rules facilitating easy community formation might not necessarily be optimal because an outcome analogous to a Chamberlinian tangency solution might result. Consequently, too many communities would exist in the sense that local public services would be provided more expensively than necessary. Following this suggestion, suppose an analyst were to judge that public services would be provided most cheaply with jurisdictions of say, 50,000 members, but observes that actual jurisdictions contain, say, 30,000 members. What inference should the analyst draw from this discrepancy between optimal size and actual size? Should the situation be called "nonoptimal," or should the presumption about optimal size be considered refuted?

The analytical proposition that the least-cost size is 50,000 members is, of course, nothing but an economist's representation of the presumed mental states of the participants in the economic process. This representation, if accurate, implies that a resident of a jurisdiction with 30,000 members would sense a personal disequilibrium. To say that an individual bears a higher cost when jurisdictions contain 30,000 members than when they contain 50,000 members is to say that this individual places a higher value on those options he must sacrifice to maintain a 30,000 jurisdiction than he places on those options he would sacrifice by switching to a jurisdiction with 50,000 members.

But if this is an accurate representation of mental states, how can jurisdictions with 30,000 members survive? Would not the survival of such jurisdictions refute the presumption of inefficiency and suggest instead that the economist had misrepresented the mental states of the participants? If the economist had developed an accurate representation, the choices actually made by the participants would necessarily have corresponded to the person's sensed least-cost option.[1]

Benefit spillovers raise the same set of issues. Suppose, for instance, that a set of governments in an urban area fail to engage in contractual relations of any form. Does the absence of such relations indicate nonoptimality as described by the standard formulation of independent adjustment equilibrium, or does it indicate only that the economist's representation of the mental states of the participants is incorrect?

If the economist's representation were correct, the so-called "independent adjustment equilibrium" characterizes a disequilibrium setting. In such a setting, an incentive exists for units of government to engage in mutually profitable exchanges, and such incentives will persist so long as the situation described by the divergence between the independent adjustment equilibrium and the optimal outcome continues to describe accurately the mental states of the participants. One possible interpretation, then, of the observed absence of contractual relations is that the postulated spillover effects are nonexistent.

Economics, as G. L. S. Shackle has noted, deals with thoughts, not with things.[2] Merely to observe a physical pres-

[1] The necessity of relating concepts of cost to the choices actually made by participants in the economic process and the impossibility of measuring cost independently of choice are developed in James M. Buchanan (1969).

[2] This is aptly expressed by the sentiment: "Economics is a branch of the study of man, and is *essentially* concerned with the nature and processes of his mind" (p. 92, Shackle's italics).

ence, then, cannot be taken as verifying the existence of spillovers. It is not physical states, but mental states with which we deal, and the latter cannot be observed directly but can at best only be inferred through observation of choices within particular institutional settings. The analyst once again merely concocts a representation of the mental states of the participants. But information as to the aptness of any particular concoction can be gained only by observing choices that actually emerge, and these choices will be constrained by the particular features of the institutional environment. The development of rationales for state activity, then, which has been the objective of the normative theorizing, is a quite different activity than the construction of an interpretation of social reality.

Compulsory public education, to select a different illustration, has often been rationalized on the basis of externalities, it being alleged that the educational level of any one person affects positively the utility level of all other persons. E. G. West, however, has developed a coherent, alternative interpretation of the emergence of compulsory schooling as an instrument for enhancing the monopoly position of the educational establishment. Relatedly, Robert J. Staaf has described how in the absence of externalities public education can nonetheless emerge through the operation of majority rule budgetary processes under certain distributions of income and tax shares. The development of a rationale, then, begs the question of the selection of an interpretation of reality.

## II. Rationalization, Refutation, and Community Formation

The customary normative analysis of local government is necessarily incapable of explaining what is at stake in choosing among alternative institutional arrangements for guiding the formation of communities and the selection of boundaries—and it is the institutional arrangements, not the "optimal" allocations themselves, that are subject to choice in the first place. This section reinforces the methodological point developed in the preceding section, and does so in part by illustrating once again the lacuna inherent in the normative approach to urban government.

There may indeed be reasons why mutually profitable trades might fail to be consummated, though the acknowledgment that this may be so shifts the analytical focus from the manipulation of normative models to the examination of alternative institutional arrangements. I, for instance, have described how the incentive to seek out and consummate mutually profitable agreements among governments will vary with such institutional features as the attenuation of ownership rights and the range of services provided by a single unit of government. In a related vein, the Governor's Task-Force on Local Government Reform (California) has noted how restrictions or prohibitions on the ability of people to secede from existing jurisdictions, and to form new ones, would act as barriers to entry, thereby altering the inferences that one might draw from observations regarding the survivability of specific practices or outcomes.

Enormous variety exists among states in the constraints placed upon the formation of local communities, and these constraints pertain to such matters as incorporation and disincorporation, annexation and disannexation, and the creation of special districts. With regard to annexation, for instance, many states require separate majority votes in the annexing city and in the territory to be annexed, while in some states a city unilaterally can annex unincorporated territory. Similar variations exist with respect to municipal incorporation. In eleven states (Connecticut, Delaware, Florida,

Georgia, Hawaii, Maine, Massachusetts, New Hampshire, New Jersey, Rhode Island, and Vermont), municipal corporations are formed by special acts of the state legislature. In the remaining states, general rules of incorporation apply either to all cities or to classes of cities. Some states even give cities the right to amend their own charters.

One of the features of particular interest is the restrictiveness of the constraints placed upon the formation of new communities. While many states permit what may be called free formation of local communities from unincorporated territory, seven states (Alaska, California, Kansas, Maryland, Minnesota, Tennessee, Virginia, and Wisconsin) tightly constrain entry by essentially giving existing localities control over the formation of new communities.

A normative model could, of course, be constructed to rationalize either practice. One might postulate, for instance, that the creation of a new jurisdiction imposes costs on other jurisdictions, and conclude that optimality requires that existing communities be given a voice in the creation of new communities. Sho Sato and Arvo Van Alstyne, for instance, oppose provisions for free entry on the grounds that the use of such provisions "tends to frustrate any rational boundary adjustment" (p. 45). One could also rationalize free entry, perhaps by arguing that it acts as potential competition to promote efficiency among existing units of government. Moreover, the agile normative theorist could even rationalize both rules simultaneously: he would simply suggest that free entry be used when the marginal gains from the promotion of competition exceed the marginal gains from the internalization of externalities, and that restricted entry be used otherwise.

The construction of rationales, however, begs the question of the appropriate interpretation of social reality. For instance, institutional rules that enable existing communities to restrict the formation of new localities could be interpreted as a practice that diminishes competitive pressures in the public sector. Such rules, then, would operate in much the same manner as would rules that gave existing grocers in some city the right to veto potential new entrants. Since the supply of rationales for some particular activity is limited only by the imagination of the analyst, analytical effort should be focused not on rationalization but on refutation of the presumptions about reality implicit in the various possible rationalizations.

California has operated under both types of institutional regimes. Before 1964 California essentially had free entry, but after 1964 it gave existing communities a veto over the formation of new communities. In each of the 58 counties, Local Area Formation Commissions (LAFCOs) were created; these LAFCOs consisted of representatives from the county and from the incorporated municipalities within the county and were given the right of vetoing the formation of new communities within the county.

While Dolores T. Martin and Wagner estimate that the creation of LAFCOs reduced by 56 percent the rate of formation of new communities, the question of interpretation revolves around the consequences of this curtailment. It could be argued that LAFCOs enabled communities to create jurisdictions of more efficient, lower-cost size. It could also be argued, however, that by reducing the constraining influence of competition in the public sector, LAFCOs allowed the actual unit cost to rise due to the enhanced survivability of X-inefficiency.

Martin and Wagner estimated a model of both total and per capita expenditure for both the pre- and the post-LAFCO periods, with the units of observation be-

ing the 58 California counties. The hypothesis of identical coefficients as between the two periods was rejected at the .05 level for total expenditure, and at the .001 level for per capita expenditure. Expenditure behavior, then, would seem to differ significantly as between the pre- and the post-LAFCO periods. Furthermore, application of the pre-LAFCO structural relationship to the post-LAFCO data to generate a prediction of what would have happened had LAFCO not been instituted suggests that LAFCO was responsible for a 17 percent increase in total expenditure and a 13 percent increase in per capita expenditure. Theodore Bergstrom and Robert D. Goodman and Thomas E. Borcherding and Robert T. Deacon find that the demand for municipal services is price inelastic, being in the vicinity of –.5. The expenditure consequences of LAFCO in conjunction with the inelastic demand for public services is consistent with the monopoly enhancing interpretation of LAFCO.

I recognize, of course, that particular results are only suggestive, not conclusive, and that there is much room for the comparative examination of alternative institutional arrangements.[3] In juxtaposition with the growing body of positive, interpretative literature on the monopolistic tendencies of governmental institutions, however, this particular result both reinforces and is reinforced by this literature.[4] But transcending issues of particular interpretation, to repeat, is the desirability of a shift in analytical emphasis from the continued spinning of normative, optimality tales to the construction of interpretations of social reality.[5]

[3] Such an institutionalist thrust informs the array of studies being undertaken by Elinor and Vincent Ostrom and others through the "Workshop in Political Theory and Policy Analysis" at the University of Indiana.

[4] For recent empirical studies of this theme, see William A. Niskanen and Wagner and Warren E. Weber.

## III. Concluding Summary

The economic analysis of local government has so far developed primarily as an institution-free collection of abstract models attempting to explore and expound various possibilities. Possibility, however, should not be confused with probability or reality, and I would suggest that the continued trituration of abstract, institutionless optimality models should be replaced by the positive analysis of alternative institutional frameworks. We, as a society, cannot choose allocations directly but can only choose institutions, and it is through these institutions that allocations emerge. It is the institutions and not the allocations, then, that should be our basic elements or building blocks, the primitives in our analytical system. In conclusion and summarization, I would second J. de V. Graaff's conclusion about normative or optimality theorizing: "I do feel very strongly that the greatest contribution economics is likely to make to human welfare, broadly conceived, is through *positive* studies—through contributing to our understanding of how the economic system actually works in practice—rather than through normative welfare theory itself" (p. 170, Graaff's italics).

[5] I am presently preparing a book-length treatment of the organization of government, written from the perspective adopted in this paper, and tentatively titled *Property Rights, Public Choice and Urban Government*.

# On the Theory of Clubs

*By* EITAN BERGLAS*

In a well-known paper J. M. Buchanan develops a general theory of clubs. He suggests that whenever the utility derived by an individual from a specific good or service is dependent on the size of the consumption group, then a club organization will supply the service efficiently while the market will not.

In this paper (Section I) we show that given the above characterization of commodities (which we regard as an important addition to the economic literature) no market failure need occur. More specifically, taking Buchanan's example, competitive firms can provide swimming pool services as efficiently as clubs.[1] Thus, Buchanan's paper does not provide a sufficient explanation for the creation of clubs.

In Section II, we extend the Buchanan model by allowing the individual to vary the number of times per season he visits the swimming pool. Once this is taken into consideration, it can be shown that providing the service on the basis of either a membership fee or a two-part tariff is inefficient; the optimal pricing system is to charge a price per visit. This will be the price when the service is provided by competitive firms.

Introducing heterogenous tastes (Section III), it is shown that individuals with different tastes will prefer to join separate clubs—and that when the service is provided by the market, the market will provide (and the consumers will prefer) different qualities of service for different types of individuals. In order to allow for the case where individuals with different tastes use facilities providing the same quality of service, it is necessary to bring transportation costs into the model—thus introducing the very complex considerations of spatial equilibrium. The problems associated with this case are discussed and partial solutions are offered. In Section IV we offer some concluding remarks, clarifying the connection with the literature on externalities and increasing returns to scale.

## I

We start by reconstructing Buchanan's model, simplifying its presentation in a way which enables us to develop it further. Suppose the economy consists of identical individuals consuming a private good $x$ (which may represent a composite aggregate of private goods) whose price is normalized to $p_x=1$, and a public good—say, a swimming pool. The benefits of the swimming pool, $h=h(y, n)$, depend on its size ($y$) and the number of individuals using it ($n$). Let the cost of the service also depend on the size and the number of users, $c=c(y, n)$. Since we start with identical consumers, we shall derive Pareto optimal conditions for the size of the pool and the number of users (the size of the club in Buchanan's paper)—assuming every individual ends up with the same utility. Our problem is therefore:

$$(1) \quad \max u[x, h(y, n)] \quad \text{s.t.} \quad x=I-c(y, n)/n$$

where $I$ denotes individual income. In order to facilitate the use of calculus, $n$ is as-

* Tel-Aviv University and the University of Rochester. This paper was written during my stay in Rochester as a Xerox Visiting Professor. I wish to thank E. Helpman for useful comments.

[1] It will be shown that the Buchanan club solution is efficient, and that the recent criticism of it by Y. K. Ng (1973, 1974) is incorrect.

sumed to be continuous in the analysis which follows.[2]

Notice that the problem defined by equation (1) may have a solution with $n=1$, which means each individual will have his own swimming pool; or even the case where max $u \Rightarrow n=0$, which means that individuals will not consume the services of swimming pools. The theory of clubs assumes that there are commodities for which congestion costs are small or nonexistent when the number of users is small, or that average costs decrease (at least over a range) so that it pays for groups to consume collectively. Furthermore, the theory implies that beyond a certain group size, congestion costs rise faster than average costs fall. Thus, the optimal consuming group $n^*$ is finite and small relative to total population $N$, or $1<n^*<N$.

In order to derive the optimal solution, assuming an internal solution, differentiate equation (1) with respect to $y$ and $n$ to get

$$nu_2h_1/u_1 = c_1 \tag{2}$$

$$c_2 - nu_2h_2/u_1 = c/n \tag{3}$$

Where subscripts denote partial derivatives, or, $u_1 \equiv \partial u(x, h)/\partial x$. Equation (2) is simply the Paul A. Samuelson rule for public goods. It is important to note that this rule should hold independently of the size of the group.[3] Equation (3) implies that if the size of the group is optimal, per capita payment, $c/n$ should equal the marginal social cost (where marginal social cost is defined as the sum of marginal maintenance cost and marginal congestion cost). Using equations (2), (3) and the budget constraint, it is possible to solve for $x^*$, $y^*$ and $n^*$. If $N/n^*=k$ is an integer, the utility of the population is maximized by the formation of $k$ identical clubs.

Ng (1973, 1974) correctly recognizes that by this maximization procedure benefits minus costs per club are not maximized. But he errs by requiring that for Pareto optimality, each club must maximize benefits minus costs. The Ng criterion requires maximization of $nu[x, h(y, n)]$ instead of equation (1). This leads to per capita $u^{**}<u^*$. Therefore, this solution is Pareto inferior. The correct criterion in cost/benefit terms is to maximize total benefits (for the whole community) minus costs; this is consistent with maximization of per capita net benefits. Therefore, the tax-subsidy scheme suggested by Ng is incorrect, and the Pareto efficiency rules derived by Buchanan are the correct ones.

Assuming that $k$ is large enough, and postponing for the moment the possibility that $k \neq$integer, the question arises: Is it necessary that the group will organize as a club? We want to argue that the answer is: no!

Suppose that swimming pool services are organized in an industry which consists of $k$ identical firms. Each firm operates a swimming pool of size $y^*$ and sells $n^*$ season tickets at $P^*_s=c(y^*, n^*)/n^*$ dollars per ticket. We want to show that this industry structure and season ticket price constitute an equilibrium for an appropriately defined decision problem for firms. We need to concentrate only on firms, since it is obvious that under these circumstances individuals will have no incentive to form clubs.

One may think of a firm as an entity which supplies swimming pool services and can control the quality of these services. The quality of these services is a function of the facility size and of the number of users. The $j$th firm is thus free to choose

[2] The following analysis is unaffected if the utility function takes the general form $u=u(x, y, n)$, and/or if $n$ is eliminated from either the utility function or the cost function. In the latter case $\partial(c/n)/\partial n<0$ for every $n$.

[3] In reality, a swimming pool cannot be characterized by one variable such as size. Given equation (2), it is straightforward to generalize the result. Let $y$ denote a vector of characteristics such as size, water temperature, purity of water, etc. Then equation type (2) will hold separately for each element in $y$.

three variables: its facility size $y^j$, the number of users $n^j$ which determines quality and the price of a season ticket $P_s^j$. However, the firm knows that it has to choose $(y^j, n^j, P_s^j)$ so as to assure its buyers of at least the utility level $u^* = u[I - P_s^*, h(y^*, n^*)]$ which is provided by other firms, otherwise it will have no customers. Hence, the firm's decision problem is: Choose $y^j$, $n^j$, $P_s^j$ to maximize

$$(4)\quad P_s^j n^j - c(y^j, n^j) \text{ s.t. } u[I - P_s^j, h(y^j, n^j)] \geq u^*$$

It is easy to see that $(y^*, n^*, P_s^*)$ is a solution to this problem. Hence, the proposed allocation and price are indeed an equilibrium.

Whenever these equilibrium conditions do not hold we have either $P_s \geqq AC$ [and $h \neq h(y^*, n^*)$ when $P_s = AC$] or $P_s < AC$. In the first case it is possible for a new firm to enter the industry and make (an above normal) profit, in the latter case firms will tend to leave the industry.

We have shown that in this case competition will lead to a stable optimal equilibrium. This is the same solution derived for a club equilibrium. Therefore, we can state that Buchanan externalities do not lead to a market failure—and that if there are advantages to organizing into clubs, further explicit assumptions are needed to establish these benefits.[4]

We now turn to the case where $n^*$ is large relative to the market, say $n^* < N < 2n^*$. In this case, any subgroup of $n^*$ people that organizes as a club will be able to maximize its members' utility. Ignoring the problems of the stability of this case, it should be emphasized that this argument in favor of a club is not an outcome of the specific Buchanan model. Suppose instead that we have a case of a private good produced by a U-shaped average cost function. Let the number of consumers that will purchase the total output of the firm, when $P^* = \min AC$, be denoted by $n^*$. Then if $n^* < N < 2n^*$, it pays any $n^*$ to organize a club. The analogy seems incomplete because, in the latter case, members of the "club" will benefit by reselling part of their share in the private commodity to nonmember consumers. This difference is not due to congestion effects but is a result of the nondivisibility assumed in the case of the Buchanan model.

In the next section, we analyze the case where club members can vary the intensity of their use of the club services. When this is done, the analogy between the Buchanan case and the case of firms with U-shaped cost curves becomes complete. Furthermore, the integer problem discussed in detail for the club model by Mark V. Pauly is reduced to the problem of an industry which consists of firms with U-shaped cost curves.

## II

Turning to the intensity of use of club facilities, it is immediately clear that intensity can be affected in various ways. In the case of swimming pools, the club member can change the number of times he visits the place, the length of his stay, and the use of the pool's various services. A member of a professional association is free to choose the activities he takes part in. In the following analysis, however, just one variable represents intensity of use; this will suffice to show the similarity between the club case and the private good case.

When the consumer is allowed to change the number of visits to the swimming pool ($v$), the utility function and the budget constraint are reformulated as follows:

$$(5)\qquad \text{Max } u[x, h(y, v, nv)]$$
$$\text{s.t. } nx + c(y, nv) = nI$$

[4] E.g., additional benefits can arise from: individual preferences with regard to the composition of the club membership, tax advantages and savings in the cost of revenue collection.

We assume that both costs and congestion are functions of the number of visits to the swimming pool ($nv$). The number of visits per consumer ($v$) appears twice in the utility function—once to represent the fact that utility of the individual depends on the number of his visits, and once to represent congestion externalities. Thus, $h_2>0$ $h_3<0$.

The first-order conditions for maximization of equation (5) are given by

$$(6) \qquad nu_2h_1/u_1 = c_1$$

$$(7) \qquad vc_2 - nvu_2h_3/u_1 = c/n$$

$$(8) \qquad u_2h_2/u_1 = c_2 - nu_2h_3/u_1$$

Equation (6) is the Samuelson condition. Equation (7) is similar to equation (3) above (which gives the solution to the optimal number of customers), except that it is corrected for the fact that congestion depends on the number of visits ($nv$). Equation (8) gives the optimal number of visits per customer. Conditions (6)–(8) and the budget constraint in (5) can be solved for optimal $x^*$, $y^*$, $n^*$, $v^*$.

Now suppose that the service is organized on a cooperative basis and that the individual is paying a membership fee of $P_m=c^*/n^*$. His optimal behavior as a club member is then

$$\max u[x, h(y^*, v, n^*v)]$$
$$\text{s.t.} \quad x = I - P_m$$

where he chooses the optimal number of visits without having control over the visits of other members. In this case, his optimal number of visits will be such that $u_2h_2=0$; his marginal utility from visits to the swimming pool will be zero, thus violating equation (8).

Suppose, instead that payment is on a per visit basis such that

$$(9) \qquad P_v = c_2 - nu_2h_3/u_1$$

where all partial derivatives are evaluated at the optimal solution given by equations (6) to (8). The individual budget constraint is now $x+vP_v=I$. Maximizing the utility function, we get $u_2h_2/u_1=P_v=c_2-nu_2h_3/u_1$, which is equation (8). Total revenues of a swimming pool of size $y^*$ that allows $n^*v^*$ visits will be $n^*v^*P_v=n^*v^*(c_2-n^*u_2h_3/u_1)$ —which, by equation (7) is equal to $c^*$.

Thus an optimal-size swimming pool charging a price $P_v$—which by equation (9) is equal to the sum of congestion costs and marginal cost—and which sells $n^*v^*$ tickets per season, will be consistent with Pareto optimality; a club operating on the basis of membership fees will not be optimal. It should be emphasized that a two-part tariff—a combination of a membership fee and a price per visit—is also inefficient. It is easy to show that the same results hold if we assume that demand is not uniformly distributed over time. In this case, it is optimal to have different prices for peak hours and regular hours. These optimal prices, which are of the nature of equation (9), cover total costs. Two-part tariff is still inefficient.

As shown, the club arrangement with membership fees is inefficient. If people prefer to organize clubs and pay membership fees, they must gain other advantages for which they pay in the form of a loss in efficiency.

## III

Until now it has been assumed that all consumers are identical. Introducing two types of individuals, we start by showing that mixed clubs are not optimal.[5] Suppose that this is not the case and that the optimal club consists of $n$ individuals of type one and $m$ individuals of type two. For $y$

[5] Different types for this case require that if segregated clubs of Section I above are formed, each type will prefer a different quality of swimming pool. In the following proof simplifying assumptions are used: (1) people do not vary the number of visits, (2) congestion is a function of the number of members and not of their composition, (3) membership fees are equal for everybody, and (4) the utility of each type of individual is the same in all clubs.

to be optimal, the Samuelson criterion must hold. Or, $nu_2^1h_1^1/u_1^1+mu_2^2h_1^2/u_1^2=c_1$, where superscripts denote the types of individuals, and each type of individual has the utility function of the form of equation (1). Now, rearrange people by forming clubs of homogeneous memberships without changing the sizes of the clubs. Since the number of people in each club does not change, and as long as $y$ does not change, everyone's utility remains unchanged. However, since $u_2^1h_1^1/u_1^1\neq u_2^2h_1^2/u_1^2$, the Samuelson criterion does not hold for the two clubs. Thus, everyone's utility can be increased by adjusting $y$ to the preferences of the now different compositions of the clubs.

This shows that once the population is large enough to justify the existence of many clubs, it is not optimal to have many identical mixed clubs. A Pareto optimal solution is to build two types of clubs by using the procedure of Section I separately for the two types of individuals. (See Pauly and Martin C. McGuire for other proofs of the same proposition.)

In this case, if the service is provided by a competitive market, we shall observe two types of swimming pools—each servicing a population with different tastes or incomes. Furthermore, it is easy to show that this result continues to hold if people can control the number of their visits.

It is interesting to investigate the conditions that lead to a case where people with heterogeneous tastes use the same swimming pool. It seems that in order to allow for this possibility, it is necessary to introduce transportation costs into the model. If consumers do not live in homogeneous neighborhoods, they may prefer a nearby swimming pool not optimally adjusted to their tastes to a distant one which provides preferable services.[6] The competitive solution for the location of firms and their optimal size has not yet been satisfactorily resolved, even under extremely simplified assumptions. (See articles by Harold Hotelling and Lester G. Telser.)

Since we are unable to provide a general solution for this case, we shall restrict ourselves to some partial observations. Suppose that people are identical except for location; suppose further that we wish to maximize utility, subject to the constraint that everybody ends up with the same utility. This implies that the club's membership shares transportation costs. Restricting ourselves to the case where intensity of use is not variable (the Buchanan case presented in Section I of this paper), the club will maximize utility by providing transportation service to its members. Furthermore, it is now necessary to add transportation costs to the cost function. Transportation costs are a function of the location of the club and the number of members. Since the number of members appears in our cost function, the solution for equation (1) covers this case if we include transportation costs in the function. It is clear that for all members it is preferable to select the location of the club so as to minimize transportation costs.[7]

However, it is much more complicated to devise full compensation schemes for heterogeneous populations. Lacking full compensation, the differential utility of customers will be affected by the location of the different facilities; it will pay people to organize a club if they can affect its location. In this case every club has some locational monopoly power. Membership arrangements can be an effective way of eliminating potential competition.

[6] The distribution of consumers in the city is regarded here as exogenous.

[7] If we allow the number of visits per member to vary, then it is optimal that every individual pay a per-visit price equal to his marginal social costs—which are the sum of marginal congestion cost, marginal service costs, and transportation. Equalization of utility can be achieved by having nearby residents pay a positive membership fee which is divided among distant members.

These observations suggest that spatial considerations may play an important role in the economic theory of clubs; further research in this direction is necessary.

## IV

We have shown that where we have both externalities in consumption and increasing returns to scale, market failure need not occur. It seems possible to suggest a generalization of the result: whenever the optimal firm providing a service is small relative to the market and exclusion is possible, the competitive market solution is possible. This formulation does not seem strange on its face; however, we have shown that it covers cases of both externalities and increasing returns to scale. In particular, it covers the Buchanan model—which seems appropriate for many situations.

It has been shown that the Buchanan case is very similar to the case where firms have U-shaped average cost functions. The similarity holds for (1) the case where the optimal firm is small relative to the market, so that competition results in many identical firms and competitive production is Pareto efficient; and (2) the case where the optimal firm is large relative to the market, then increasing returns are dominant and the competitive markets fail.

INCOME DISTRIBUTION IN DEVELOPING COUNTRIES

# Toward an Adequate Long-Run Model of Income Distribution and Economic Development

By SHERMAN ROBINSON*

This paper has two purposes. The first is to present a strategy for constructing long-run, economy-wide models of developing countries. Second, the paper will outline the components of one possible long-run model which includes the distribution of income. The intent is to provide a modeling framework that can incorporate a number of different types of behavioral submodels in a mutually consistent and interactive manner. The overall framework is explicitly designed to take account of the fact that the component submodels differ widely in their specification of adjustment mechanisms and in their definition of temporal equilibrium.

Any long-run model of a developing country, and especially one which includes the distribution of income, must incorporate a wider range of economic and demographic relationships than is usual in even the largest economy-wide models. It is necessary not only to work with both the income and product accounts, but also to include the interindustry, demographic, and perhaps the household accounts as well. In recent years, Richard Stone and others have been working on developing a system of unified demographic, economic, and social accounts for the United Nations. This work is well advanced and there has been some consideration of the potential of these accounts for broader models of the economy. See Stone (1970, 1973) and United Nations.

The discussion below presents the structure of a model of income distribution and economic development in the long run. The particular model sketched here is designed to include a number of factors which recent empirical work indicates are important. It is based on two different existing models: one developed by Adelman and Robinson and a model developed by a team at the International Labour Office (*ILO*). (See M. J. D. Hopkins, G. B. Rodgers and R. Wéry.) The Adelman-Robinson model is short-run while the *ILO* model is long run. Indeed, the framework presented here can be used to integrate the two different models.

Both the Adelman-Robinson and the *ILO* models yielded similar results which are also largely consistent with other work.[1] Since these results are based on models of two countries—South Korea and the Philippines—they can be thought of as hypotheses which should be tested in other countries and so should influence models designed to study distribution and

development. Some of the major results are summarized below. The reader who wants a fuller description, including appropriate qualifications, can consult the original studies.

—The studies support the Kuznets U hypothesis that during development the distribution will initially become more unequal and only later become more equal.

—The basic time path of the household distribution is very stable and quite difficult to change by policy intervention.

—The functional distribution is quite unstable and is strongly affected by policy intervention. The functional and size distributions do not necessarily move together.

—The effects of single policies are quickly dissipated. Although the effort required is large, broad based economy-wide policy packages can have significant effects on the distribution. A corollary is that interaction effects and nonlinearities are very important. The overall impact of a policy package is different from the sum of the effects from the separate components.

—Long run or complete adjustment results are often very different from short run or partial equilibrium results.

—In the short run, wage and price adjustments are more important in determining the distribution than are quantity adjustments in both factor and product markets. In the product markets, variations in the agricultural terms of trade have the strongest impact on the distribution.

—Among the quantity adjusting variables, interregional migration, skill upgrading, and education are important in their distributional effects.

These results, along with the general characteristics of developing countries, suggest a number of factors that should be incorporated into any long-run model which includes distribution and also some of the broad design characteristics of such a model.

## I. Desiderata of a Long-Run Model

First, a long-run model should be in the broad tradition of multisector planning models. Existing multisector economy-wide models have, with varying degrees of success and realism, embodied sectoral growth, changes in the structure of production, and changes in the structure of employment.[2] In a long-run model, it would be well to reduce the number of sectors and concentrate instead on incorporating demographic interactions, migration, and changes in the skill structure of the labor force (through education and nonformal training.)

Second, any model which attempts to address distributional questions should endogenously determine both wages and prices. Wage and price endogenous general equilibrium models (*WPE* models) are currently available and can be implemented.[3] In a *WPE* model, the model economy is essentially Walrasian with profit maximizing producers and utility maximizing consumers interacting across product and factor markets. It is a general equilibrium model which solves for wages and prices so that, given nonlinear supply and demand relationships, all product and factor markets clear. The solution problem is that of finding a fixed point for a set of very nonlinear equations in wages and prices.[4]

Third, a distributional model must, in fact, generate the distribution of income in detail. An economy-wide model will naturally generate the functional distribution, at least by broad functional categories such as wages, profits, and rent. An ade-

[2] For a survey, see Charles R. Blitzer, et al.

[3] See Adelman and Robinson, F. Ahmed, K. Dervis, and Lance Taylor and F. Lysy.

[4] For a discussion of solution techniques, see Adelman and Robinson.

quate model, however, should generate the functional distribution in some detail including many income recipient groups and also generate the entire distribution by individual income recipients. A model should also generate the size distribution of income by households and thus explicitly model the grouping of income recipients into households. This is done in the Adelman-Robinson model. For related techniques, see Hopkins, et al., and Erik Thorbecke, and Jati Sengupta.

Finally, a question that must be dealt with in formulating a long-run model is how to incorporate the fact that different parts of the economic system adjust at very different rates. There is an explicitly dynamic problem in defining the nature of equilibria in a model which seeks to describe a developing country over an extended period of time. A long-run model must deal with two different kinds of adjustment behavior. First, there are markets such as product markets in which prices and quantities adjust quickly and excess demands are reduced to zero within a relatively short period. Second, there are markets in which excess demands or supplies can persist for an extended period. For example, continuing technological change in industry and continuous lags in investment and migration responses may cause marginal products in the urban sector to be above those in the rural sector for a long period of time.[5] In a long-run model, it is thus necessary to model the disequilibrium behavior of these markets and so explicitly model the laws of motion of the dynamic economy.

The disequilibrium dynamics required of a long-run model can best be represented by quantity adjustment models (following Janos Kornai). Short period disequilibrium reflects both price and quantity disequilibria and, in the usual analysis, prices will adjust to clear the market by moving factors along their supply and demand curves. One can assume that factor immobility will persist in the short run and will result in differential wages and rentals among sectors. In the long run, one must model the quantity response to the disequilibrium which is reflected in the short-run differential wages and rentals. The experience of many economies suggests that full equilibrium is never reached; i.e., that wages and rentals are not equated across sectors and regions, even over long time periods.

## II. Structure of a Long-Run Model

This section outlines a proposed structure for a long-run model. The structure proposed here is intended to encompass a number of different interacting component models in a unified framework.

The model framework is presented schematically in Figure 1. In each period, the solution of the overall model is divided into two stages. In the particular models diagrammed here, the Stage 1 model is a *WPE* general equilibrium model whose solution gives as outputs: production, employment, wages, prices, and the distribution of income. The *WPE* model framework is flexible enough to accommodate a wide variety of behavioral assumptions and institutional constraints. The Stage 2 model consists of a number of sub-models which take as inputs different parts of the Stage 1 solution and yield as output the quantity response of factor supplies and all other exogenous variables needed for Stage 1 in the next period. Six different sub-models are listed in Figure 1 with varying degrees of linkage to the Stage 1 solution and among themselves.

In order to understand the division between Stages 1 and 2, there are three notions of equilibrium which need to be dis-

[5] See M. Bruno and Robinson for examples of two-sector disequilibrium growth models.

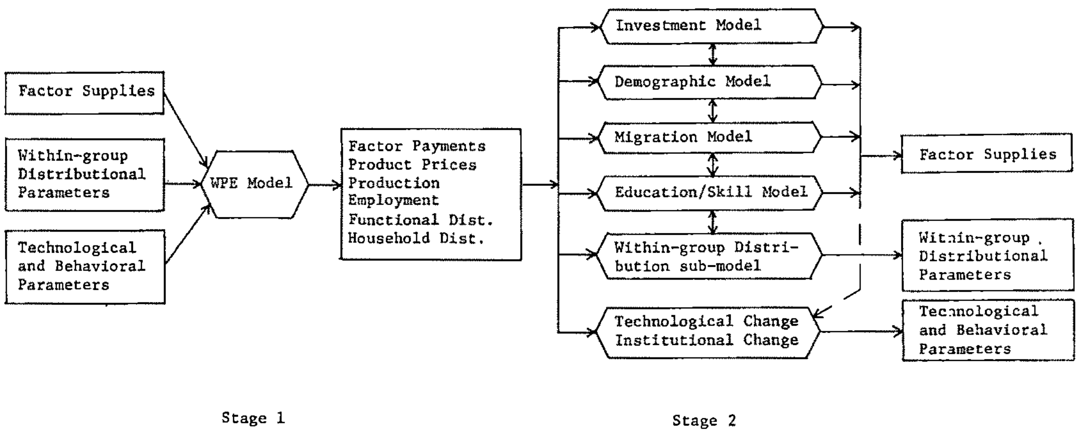

FIGURE 1

tinguished. First, in Stage 1, short-period equilibrium is defined as zero excess demand in product and factor markets subject to a number of constraints on factor mobility. The operation of these constraints leads to sectoral differentials in wages and rates of return to capital in place. The elimination of such differentials defines a second notion of equilibrium, that of full neoclassical equilibrium. Full neoclassical equilibrium is not attained in Stage 1; indeed, the solution of Stage 1 describes the degree of factor price disequilibrium. The third notion of equilibrium is that of intertemporal or long-run equilibrium in which all expectations are validated and in which the first two types of equilibrium prevail continually. The Stage 2 model consists of a number of different quantity adjustment submodels which, when solved together, yield the response of factor supplies to the situation described by the solution of Stage 1. The solution of the two stages yields neither full neoclassical equilibrium nor full intertemporal equilibrium, although the Stage 2 quantity adjustment submodels should move in an equilibrating direction.

The distinction between Stages 1 and 2 is really one of different adjustment rates. In Stage 1, factor supplies are assumed fixed, where "fixed" may have a number of different meanings. For example, one might assume that labor and capital are completely immobile among sectors, or one might assume that they are partially mobile. One might also assume that some wages are fixed exogenously in the tradition of two-sector excess labor models. (See Dervis and Ahmed.) The Stage 2 submodels together describe the dynamic response of the economy. Their specifications will clearly depend on the nature of the constraints imposed in Stage 1. For example, the migration model would be very closely related to the Stage 1 model, with migration being a function of regional income differentials. The investment model requires two components, one to determine aggregate investment (and savings) and one to determine the sectoral and regional allocation of investment, which should clearly respond to the differential rates of return solved in Stage 1. The challenge is to model the degree of response.

The educational, demographic, and migration submodels are shown as being interrelated. The *ILO* model is perhaps the most satisfactory current model in including the various interrelationships. Stone (1970, 1973) and Frederic Shorter are

examples of alternative models. Of the three submodels, the migration model would be the most sensitive to the solution of Stage 1. A general framework for incorporating the interrelationships among the submodels is suggested in Robinson and Dervis.

The technological and institutional change submodels are shown as interconnected with the other submodels. Given the current state of knowledge, this represents more wishful thinking than a reflection of existing models. The roles of technological and institutional change in growth—especially as they differ by sectors and regions—are among the least well understood economic processes and among the most important.

There are a number of different ways in which the distribution of income can enter the model stages. Following Adelman-Robinson, it is possible to have the Stage 1 model solve for the mean incomes of a number of different functional groups and generate the overall distribution by assuming known frequency distributions for the within-group distributions whose parameters are specified exogenously to Stage 1. In the diagram, these would be the exogenous distributional parameters shown feeding into Stage 1. The overall distribution is calculated by simply summing the intergroup distributions whose parameters are known. A Stage 2 submodel would update the exogenous distributional parameters, either independently or as a function of the Stage 1 solution. How the within-group distributions vary over the long run is not well understood either theoretically or empirically and represents a potentially fruitful area for further research. One possibility, for example, is to argue that the within-group distributions are a function of the age and education structure within a given skill or functional category. Thus changes in the within-group variance of income might be specified as a function of changes in the within-group age and educational structures which are generated by the educational and demographic submodels.

## III. Conclusion

There are currently no long-run models that fit into the framework presented here. The Adelman-Robinson model is explicitly a short-run model but does incorporate the basic idea of modelling stages presented here. Being a short-run model, it concentrates in Stage 2 on the investment and migration submodels and incorporates a number of financial and monetary effects. The *ILO* long-run model incorporates many of the Stage 2 submodels but has a much simpler Stage 1 (not a *WPE* model). There are also *WPE* models which incorporate some of the Stage 2 components directly into the Stage 1 models, remaining within an explicitly equilibrium framework. For example, see Dervis and Ahmed.

The modelling framework proposed can be used both for building new models and for classifying existing ones. For example, within this framework, the J.R. Harris-M.P. Todaro migration model can be seen as an attempt to view migration as an equilibrium process that can be modeled in Stage 1 rather than as a disequilibrium adjustment that is better modeled in Stage 2.

The separation of market clearing and quantity adjusting dynamic models into two distinct stages should permit much more realistic modeling of dynamic processes. The distinction between equilibrium and disequilibrium models has been widely recognized and is currently being used by those who work with Keynesian macro-models (who, however, consider a single set of markets and compare short-run disequilibrium with long-run equilibrium). With the development of *WPE*

general equilibrium models, builders of planning models can now exploit the notion and, at the same time, expand the boundaries of their models.

# Income Distribution and Development: Some Stylized Facts

By MONTEK S. AHLUWALIA*

In recent years, the relationship between income distribution and the process of development has come under increasing scrutiny. Much of the debate has focused on the hypothesis, originally advanced by Simon Kuznets, that the secular behavior of inequality follows an inverted U-shaped pattern with inequality first increasing and then decreasing with development. This hypothesis has become so much a part of the conventional wisdom on this subject that it has generated considerable skepticism about the welfare implications of the development process. Indeed, on some interpretations, developing countries face the grim prospect not just of increasing relative inequality, but also of declining absolute incomes for the lower income groups.

The object of this paper is to reexamine the empirical basis for this hypothesis, using a recent compilation of cross-country data.[1] We have used multiple regression to estimate cross-country relationships between inequality, as reflected in the income shares of various percentile groups, and selected explanatory variables reflecting different aspects of the development process. Needless to say, associational relationships of this type do not establish causality. They are better described as "stylized facts," which can be observed, but which then need to be explained by an appropriate theory.

## I. Short and Long Term Relationships

As a first step, it is useful to distinguish between two types of relationships that might obtain between income distribution and development; there may be a long-term or secular relationship between the degree of inequality and the level of development, and there may be a short-term relationship between inequality and the rate of growth. Both types have been discussed in the literature, but the importance of distinguishing between them has not been adequately recognized.

Kuznets' hypothesis clearly referred to a secular relationship generated by long-term changes in economic structure. It was, after all, based on an observed trend in this century towards a reduction in inequality in some of the now developed countries, which Kuznets contrasted with the "more probable" trend of widening inequality in the early stages of their industrialization. In contrast with this type of long-term relationship, some of the recent debate has focused on much more short-term phenomena. Thus it has been suggested that high growth rates in some less developed countries (*LDC*), observed over comparatively short periods, e.g., Brazil between 1960 and 1970, have led to a marked increase in income inequality. While such an outcome can be explained simply in terms of Kuznets' hypothesis—a higher rate of growth raises

* Development Research Center, World Bank. I am indebted to Marienne Lehwing for computational assistance. The views expressed in this paper are those of the author and not of the World Bank.

[1] Income distribution data for 62 countries (including 14 developed countries and 6 Socialist countries) were taken from a recent compilation of available data (see Shail Jain). Data on explanatory variables for years corresponding to the observations on income distribution are taken from the World Bank's data files.

the level of development, which in turn affects inequality—it is noteworthy that the debate on this issue has a somewhat different flavor. There is a distinct suspicion that there are short-term forces operating independently of the long-term phenomenon which generate higher inequality as a consequence of faster growth. For example, if growth is concentrated in particular regions or sectors (as is very likely to be the case), then lags in labor mobility may create factor market disequilibria which generate significant income differentials. It is easily seen that such differentials need to be distinguished from income differentials reflecting long-term structural factors such as the scarcity of labor skills. They are superimposed on the structurally determined income differentials and may be seen (and are often defended) as necessary lubricants to overcome some of the frictional resistance to the pursuit of high growth rates.

We can test for each of these relationships by appropriate choice of explanatory variables in our regression equations. The secular relationship can be tested by including per capita *GNP* (in various transformations) as an explanatory variable and the short-term relationship can be tested by including the rate of growth of *GDP* over the past ten years as an additional explanatory variable. The relevant findings of our cross section analysis can be summarized as follows. See equations (1a), (2a), (3a) and (4a) in Table 1.

(1) There is substantial confirmation of a statistically significant relationship between the income shares of various percentile groups and the logarithm of per capita *GNP*. Furthermore, the relationship is clearly not monotonic since a significant relationship is identified only when the per capita *GNP* variable is entered in quadratic form. This formulation generates the familiar U-shaped pattern: the income share of the lower income groups (alternatively defined as the lowest 60 percent and the lowest 40 percent) first declines and then rises with increasing per capita *GNP*, while the share of the upper income group (top 20 percent) describes the opposite pattern. Similar results have been reported by Irma Adelman and Cynthia Morris and Hollis Chenery and M. Syrquin.

(2) By contrast, there is no evidence of an independent short-term relationship between the level of inequality and the rate of growth of *GDP* over the recent past. The coefficient on this variable was insignificant in all the equations estimated in experimenting with alternative functional forms and different combinations of other explanatory variables.

The lack of a significant relationship between inequality and the rate of growth is potentially important in defining the nature of the relationship between distribution and development. It suggests that while there may be a secular time path for inequality which developing countries must traverse and which contains a phase of increasing inequality, there is at least no evidence that faster growing countries show higher inequality at the same level of development than slower growing countries. If this is true, policymakers are perhaps best advised to think of the rate of growth as determining essentially the speed of transition through the different phases of development and inequality: higher growth rates accelerate the transition without necessarily generating greater inequality than can be structurally expected in each phase.

We hasten to add that our cross-section results provide only weak evidence for this point of view. For example, we cannot deny that particular types of growth

processes may have markedly adverse effects on inequality. The cross-section evidence only establishes that fast growers do not systematically display any such pattern i.e., if there are countries in which this is true, there are others whose experience is of the opposite variety. Recognizing this diversity of experience is perhaps the most important lesson to be learned from the data. At the very least, it shifts the focus of debate away from a naive (and quite possibly dangerous) suspicion of high growth rates as such towards an examination of the particular nature of growth in different countries and the implications of different types of growth for inequality. Inquiries along these lines must figure high on any agenda of research on income distribution, but until their results persuade us to the contrary, the verdict on growth rates need not be unequivocally pessimistic.

## II. The Secular Relationship

We now turn to a more detailed examination of the long-term or secular relationship identified above. The observed U-shaped relationship between inequality and per capita *GNP* obviously reflects the net effect on inequality of a number of structural changes occurring with development. The nature of these changes has been extensively discussed in the literature, albeit only in general terms.[2] One of the mechanisms generating an increase in relative inequality in the early stages of development is the shift of population from the low income, slow growing, traditional sectors to the high income, faster growing, modern sectors of the economy. The difference in mean incomes between sectors suffices for such a process to produce a phase of increasing inequality, and this tendency is further reinforced if the modern sectors are also characterized by greater within-sector inequality. There are other factors which operate to reverse the process of increasing inequality in the later stages of development. For one thing, as the modern sector expands, it absorbs larger proportions of the labor force into high income employment, thus reducing the pressure of population in the traditional sectors and thereby narrowing intersector income differentials. Equally important, there are long-term forces which operate to reduce inequality within the modern sector. The cumulative impact of an expanded education system and a long established modern sector is to create a highly trained labor force with a more equal dispersion of skills which generates both an increase in the share of wage income as well as greater equality in its distribution. This tendency is further strengthened by improvement in labor organization.

We have attempted to quantify the impact of some of these mechanisms by including in our regression equations selected explanatory variables which reflect these structural changes. In general, we find that explanatory variables reflecting expansion in education, diminution of demographic pressures, and changes in the structure of production in favor of the modern sector are significantly related to the observed cross country patterns in inequality. The inclusion of these variables, in addition to the quadratic in per capita *GNP*, substantially improves the percentage of variation explained by the regression equations. See Table 1, equations (1b), (2b), (3b) and (4b). Our findings can be summarized as follows:

(1) Improvements in the quality of human resources have long been thought to be a major force for reduction in inequality. (See especially, Adelman and Morris). Measuring improve-

[2] Systematic historical studies of their impact in particular countries have yet to be conducted—the lack of time series data being a major limitation.

TABLE 1—CROSS-COUNTRY REGRESSIONS EXPLAINING INCOME SHARES
(Values in Parentheses Are T Ratios)[a]

| | Dependent Variable: Percentage Income Shares | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Top 20 Percent | | Middle 40 Percent | | Lowest 60 Percent | | Lowest 40 Percent | |

[a] For our sample, a T value of 1.68 indicates significance at the 10 percent level for a two-tailed test.

ments in this dimension obviously poses formidable conceptual and empirical problems. At the very least, we need data on the skill structure of the labor force, but even this is not available for most of the countries in our sample. We have therefore experimented with the literacy rate and various definitions of the school enrollment rates as explanatory variables roughly reflecting the quality of human resources. As shown in Table 1, improvements in literacy have a beneficial impact on the income share of the lowest 40 percent while the secondary school enrollment rate has a beneficial impact on the income share of the middle 40 percent, probably reflecting the exclusion of the lower income groups from access to schooling. It is important to note that in each case, the increase in income share occurs at the expense of a reduction in income share of the top 20 percent—an unambiguous improvement from a welfare point of view. We note in passing that in the case of the middle income groups the inclusion of education as an explanatory variable has the effect of making the per capita *GNP* variables insignificant.

(2) There are strong a priori reasons for supposing that demographic pres-

sures have an important impact on income inequality. High growth rates of population are likely to generate greater inequality by perpetuating the phenomenon of "surplus labor," in the sense that a large proportion of the work force remains locked into low income employment in the traditional or informal sectors of the economy. The cross-section results provide substantial support for this point of view. The rate of growth of population is highly significant as an explanatory variable in all our equations, and as we would expect, it has an adverse effect on the income shares of the lower and middle groups while raising the income share of the top 20 percent.

(3) We find some support for Kuznets' original suggestion that changes in the structure of production provide a mechanism through which development affects inequality. The process Kuznets had in mind has two aspects —declining relative importance of agricultural production in total output, and a shift in population from the low income agricultural sector to the high income modern sector. We have modeled each aspect separately by using two explanatory variables, the share of agriculture in total *GDP* and the share of urban population in the total population. We find that each variable is significantly related to the pattern of inequality but their effects on the income shares of different groups are not identical. The share of agriculture in *GDP* is not significantly related to the income shares of the lowest groups, but it is positively related to the income shares of the middle groups and negatively related to the income shares of the top 20 percent [equations (2b) and (1b)]. By contrast, the share of the urban population in the total has no effect on the income share of the middle group, but it is positively associated with the income shares of the lowest groups and negatively with the income share of the top 20 percent [equations (3b), (4b) and (1b)]. This suggests an interesting asymmetry in the distributional impact of structural change. As the share of agriculture in *GDP* declines with development, there is a relative shift of income away from the middle and towards the upper groups. Alongside this process, however, development also generates a shift of population to the modern or urban sectors, and this process, appears to favor the lowest income groups at the expense of the rich. This asymmetry between the impact on the middle and lower groups is not entirely implausible. At some risk of stretching our evidence too far, we can speculate that the decline in relative importance of agriculture is likely to have its strongest impact on small and middle sized landholding cultivators who may dominate the middle income groups, while the parallel process of increasing urbanization favors the low income population because it reflects increased employment in urban areas and a reduced pressure of population in the rural areas.

(4) Finally, we find that socialist countries display markedly greater equality than others as shown by the positive and significant coefficients on the dummy variables in equations (3a), (3b), (4a) and (4b).

These findings provide some clues to the casual mechanisms that lie behind the conventionally described U-shaped behavior of inequality. They are no more than clues because the essential complexity of a dynamic process cannot be

captured by the variables used in our analysis, which appear to produce a worsening of relative inequality in the early stages of development.

### III. Relative Inequality and Absolute Impoverishment

This prospect of declining income shares of the lower income groups raises obvious questions about the welfare aspects of development. In pursuing these questions, we should distinguish between two alternative views of the underlying process. The pessimistic view holds that this pattern reflects a process of absolute impoverishment of lower income groups in developing countries. (See for example Adelman and Morris.) Such an outcome cannot be ruled out a priori. It may result from an erosion of traditional economic structures against the impact of an aggressively expanding modern sector, competing against traditional sectors both for markets and resources. The resulting disruption of the preexisting economic system could lead to absolute impoverishment for some groups. There is, however, another view of the process that is somewhat less pessimistic. On this view, the worsening in relative inequality occurs not because there is a decline in the absolute incomes for the lower income groups but because rates of growth of income are lower than for upper income groups. Thus if development occurs through opportunities for economic expansion becoming available initially to upper income groups, and if these groups have relatively weak income linkages with lower income groups, we would expect development to be accompanied by an increase in relative inequality, although no absolute impoverishment need occur. The essential distinction between these two views lies in whether we assume that the disruption of low income traditional economic activities is an essential precondition for growth of the modern sector, or whether the problem is primarily one of insufficient linkage. In the latter case the problem appears somehow more tractable since we are no longer dealing with an inherent contradiction in the development process.

Cross-section analysis cannot take us very far in choosing between two such opposite views of the development process; the choice raises issues which are central to our understanding of the nature of development and these issues call for much fuller theoretical and empirical investigation. But, in keeping with our stated objective, we can at least document the stylized facts of cross-country experience. A crude measure of the average absolute income level in each percentile group can be obtained by multiplying the ratio of income shares to population shares of the group by per capita *GNP* of the economy (data on per capita personal income, which is the correct variable to use, are not available). Using equations (3a), 3b), (4a) and (4b) to estimate income shares of the lowest 60 percent and lowest 40 percent at different levels of per capita *GNP*, we can obtain estimates of absolute income levels in these groups at different levels of development. None of these estimates shows any decline in the absolute average income of the poor as per capita *GNP* rises. Alternatively, we have used the actual income share data to estimate the average absolute income of the lowest 40 percent and the lowest 60 percent. This estimate of average absolute incomes of the poor was then used as a dependent variable (in logarithmic form) in cross-country regression equations. Testing for a quadratic relationship with the logarithm of per capita *GNP* for the economy as a whole, we find that the negative term in the quadratic is not significant. This suggests that while there is substantial support for the hypothesis that relative inequality increases in the early stages of

development, the cross-country evidence does not support the stronger hypothesis that there is also an actual decline in the absolute income level of the poorer groups in this phase.

We should be careful not to read too much into this finding. Clearly, the percentile groups are very large and the observed behavior of average incomes for such groups may hide significant declines in the absolute incomes of particular socioeconomic groups which may be offset by above-average growth in income for other groups. Besides, the relationships discussed above are at best descriptions of "average" cross-country behavior; leaving ample room for intercountry differences. Nevertheless, it is important to record that the stronger hypothesis of declining absolute incomes for large sections of the population is not so unequivocally established by cross-country data as to be uncritically accepted as one of the "stylized facts" about development.

# Uneven Development and Dependent Market Economies

*By* Michael H. Best*

This paper addresses the issue of inequality from a historical perspective and is organized around three themes. First, a country's factor endowments are not determined exogenously but by powerful systemic forces, one of which is the nature of a country's integration into the world economy. Second, the class structure in the periphery mediates between the imperatives of accumulation in the center and factor endowments in the periphery. Third, income distribution in the periphery is tied to the international division of labor and the corresponding patterns of commodity specialization. Based on the analysis presented, implications for inequality-reducing strategies within poor countries are explored. The basic conclusion is unequivocal: a sharp reduction in inequality requires far-reaching structural changes in the relations of production.

## I. Growth in the Center and the Formation of Periphery Endowments

The conditions for rapid and sustained capital accumulation in Western Europe were forged by the historical conjuncture of three interdependent factors: a propertyless labor supply, a capitalist class or state in command of the productive forces and favorable economic relationships with militarily weaker regions of the world. Interactions with other regions provided important elements in the structural foundations of expansion in West Europe. The spread of commerce undermined the social relations that governed the feudal mode of production and stimulated the market relations of commodity production; in the process population moved from the land to the burgeoning capitalist enterprises. Expansionary forces within the centers created pressures for the opening of new territories for precious metals and other cheap or strategic raw materials, for investment opportunities and for market outlets. National rivalries, in part engendered by this expansion, in turn intensified it.

The crucial factor in establishing commodity production, a cheap labor supply, was recruited in the hinterland by a massive displacement of population both within and between hinterland regions. Besides the ubiquitous migrations that accompanied the penetration of market oriented production within the hinterland regions, many of the dislocated people were removed from their continental shores including 30 to 40 million Africans transported to the Americas; indentured Indian labor shipped en masse to Malaya and Ceylon, and in lesser amounts to Trinidad, British Guiana, Jamaica, East Africa, Mauritius and Fiji; and Chinese labor imported to mine gold in South Africa and to build railroads on the West Coast of North America. A variety of labor recruitment mechanisms ensured labor force dependence upon landlords and mine owners including slavery, servitude, share cropping, debt peonage, vagrancy laws, and wage-labor itself. The labor reserve was

* Associate Professor of Economics, University of Massachusetts, Amherst. I wish to thank Jane Humphries and Stephen Resnick for discussion of these and related topics and Nancy Folbre and Rick Wolff for comments.

replenished by ruinous competition from metropolitan substitutes for traditional products, the extensive control of available land by upper class groups which limited landholding opportunities for the working population, and, as will be discussed later, by high birthrates.

The integration of the hinterland into the merging world economy did not, as expected, induce capital accumulation in the hinterland. While the expansion of markets did create the potential for hinterland capitalist development, it also generated a class structure that blocked hinterland accumulation. Whereas in the center production was dominated by an industrially based bourgeoisie, in the hinterland the forces of production were controlled by a derivative owning class composed of planters, merchants, and mineowners. None of these groups became an autonomous force propelling accumulation. Instead they were interlocked with and subservient to the owning classes of the center; their fortunes were dependent not upon the vitality of the domestic economy but upon the pace of center expansion. Once primary product specialization was established, free trade and entrenched domestic interest groups were often sufficient to block the diversification of hinterland economies; in other cases mercantilist tariff policies and military force were required. Furthermore, the widespread evolution of nonwage-labor systems of labor recruitment impeded the functioning of capitalist labor markets and contributed to a persistent unevenness in productivity across regions, sectors and enterprises.

In short, the specific forms of world specialization and trade that emerged were caused less by "natural" endowments than by an international political context in which the dynamics of capitalist accumulation governed product choice and imposed factor endowments on the hinterland. The mechanisms which established product specialization and labor recruitment varied from region to region, but the consequences were similar: an international division of labor was created in which the hinterland specialized on primary products and the center on industrial commodities.

## II. Class Structure, Commodity Specialization and Income Distribution

The metropole/hinterland class differences are reflected in and reproduced by the historical dichotomy in patterns of commodity specialization, patterns that set into motion forces with very different implications for accumulation and income distribution. Specialization in industrial commodities and capital goods opened possibilities for product diversification, enhanced the introduction of new technologies and product cycles which imparted a dynamic expansionary thrust to the economy, and generated a level of labor income sufficient to stimulate the production of mass produced industrial commodities.

The dynamics of primary product specialization imposed a different experience on the hinterland. Such production, comprising an isolated segment of a center's productive system meant that in the hinterland linkages to other production stages and diversification to other product lines were limited. Concentration on cash crop exports made the region increasingly dependent upon foreign sources not only for manufactured commodities, capital, and invisibles but basic foods as well. In addition, the landowning class was not driven to accumulate capital and innovate by competitive pressure and the threat of technological obsolescence and financial ruin as their industrial brethren of the centers. Technological advancements were thwarted also on the minifundia by the small scale of production.

Primary commodity specialization and the hinterland class structure tended to

cumulatively reinforce each other. The dependence of labor on planters and mineowners for employment generated an extremely unequal distribution of income with a working class market too small to stimulate local production of manufactured goods, yet a large upper class demand for luxury imports which increased the dependence upon traditional exports. The limited employment opportunities in manufacturing ensured the dependence of the labor force upon planters and mineowners and depressed labor costs.

The post-World War II period of spreading political independence and nationalist movements ushered in a series of technician type, progress-oriented governments that systematically sought to generate an environment by which landed and merchant surplus could be transformed to industrial capital through a variety of trade, fiscal, and monetary measures. However, given the class configurations, international environment and capital intensive bias of imported technologies, the process created artificial industrial monopoly capital which was soon stalled by the chronic impediment to capitalist expansion: the tendency for productive capacity to overshoot effective demand.

The historic remedies to realization problems are less appropriate for today's poor countries. Expanding foreign sales are made difficult by the intense competition for exports amongst advanced capitalist countries all burdened by excess productive capacity, by the oligopolized and partitioned marketing channels dominated by the multinational corporations, and by protectionist government tariff and subsidy policies within the industrialized centers. Expanding internal sales by Keynesian income redistribution measures, given an elastic demand for a single country's primary product exports, would likely induce a foreign exchange crisis by driving down the sales of traditional exports both from higher labor costs and expanded domestic consumption and by increasing the demand for imports.

The post-World War II period has witnessed a shift in the locus of control toward the multinational corporations. Given their near monopoly over finance capital and technology the multinationals, without mediation, determine employment, product choice, investment, and pricing decisions and directly extract surplus through transfer pricing and fees for technology, licenses and other services. Furthermore, as recent events in Chile illustrate, when political order and the historic class configurations are threatened, owners of foreign capital continue to work in alliance with local and home government police and military agencies to maintain the status quo.

This period has also seen the continuation of another pressure from the center, mediated through the hinterland class structure, on factor endowments in the hinterland. During the process of industrialization, center countries experienced a strikingly similar demographic transition. Death and birth rates dropped from a position of balance of roughly 40–50 per thousand to a position of near balance in which a decline in birth rates to 15–20 per thousand followed within a few generations an earlier decline in death rates to 10–15 per thousand.

In the primary producing areas one side of this demographic transition took place. The need for labor in the hinterland contributed to the transfer and development of medical techniques designed to cut death rates to levels comparable with the centers. But a drop in birth rates never occurred. Instead, the commonly cited explosion in hinterland population levels has contributed to the increasing per capita income gap between rich and poor countries.

Birth rates have not dropped for good

reason. Given the class structure the only avenue for lower class people to improve family income and obtain security in old age is to have a relatively large family whose members can either work land and generate savings for the family or emigrate to the city and send back remittances which can then be used to acquire additional land and economic security. A social system based, instead, on cooperative ownership of property and social appropriation of surplus does not place on the family alone the burden of generating an income stream, meeting the costs of an education, providing social security for old age, and saving for unforeseen health needs or economic advancement. Creating social institutions to share their burdens takes pressure off the family. Alternatively in a private market system a family is forced to respond to social problems which originate in the sphere of production with individualistic adjustments in personal behavior. One of the few private responses available to people in poor market countries is the size of the family. The relative ineffectiveness of numerous progeny as a remedy for social problems implies less about sexual drives, time horizons, or intelligence of the people than about the limited responses available for dealing with such problems under private market systems.

## III. Inequality Reducing Structural Reforms

The preceding has two basic implitions for social change. First, the path followed by now rich countries is not open to contemporary poor countries. Most are not likely to benefit by the international transfer of surplus or enhancement of conditions for accumulation from a hinterland weak in military and strong on raw materials as the early industrializers did. Second, reductions in income equality will require profound structural changes. Liberal reform measures are constrained by the dependent production system and the internal class configurations. Therefore within the market rules of the game, income redistribution to labor would threaten to reduce surplus production allocated to export and investible surplus needed for capital accumulation.

A growth strategy committed to sharp reductions in inequality would involve structural changes in the purpose of production and the labor process along the following lines. First, production for use would replace the system of production for profit. A central plan with control over the general lines of development must be integrated with decentralized, largely self-reliant local units. Given the widely divergent latifundia/minifundia productivity rates, land reform will go some way to creating reorganizational space, increasing labor productivity and providing basic food needs. However, breaking down the urban/rural disparities also requires emphasis on rurally located light industries, produced in small to medium sized enterprises and applying traditional and intermediate technologies. The development of an integrated local and national social organization committed to producing a basic consumption bundle for the mass of the population can put people to work not in expanding exports of primary products or production of upperclass consumption goods, but in producing irrigation facilities, nutritious food, preventative health care, transportation systems, and ecologically sound and publicly accessible technologies.

Keynesian reforms fall short of production for use and tend to be self-defeating in the context of poor countries. For example, large scale public employment programs within a system dominated by production for profit can only channel resources into endeavors that do not threaten

entrenched private interests; as a consequence productivity rates are usually low which, in turn, soon generate inflationary and foreign exchange pressures and a call for government retrenchment. To the extent products are modified and production is reorganized to meet the needs of the underprivileged, both the scope of inequality and the long-run dependency upon foreign markets and multinational corporations will be reduced. Clearly the primary obstacle to production for use is the political power held by owning classes.

Second, the wage-labor system must be replaced with a cooperative labor system. The former is defended by neoclassical economics on the grounds that individual, external incentives, usually in the form of money, are necessary to motivate labor. Rooted in the individualistic theory of human nature, it presumes that an individual factor's contribution to a social process can be isolated and measured and ignores the inner connections between income distribution, incentive systems and worklife organization. An alternative *social* theory of human nature holds that substantial inequality does not reflect universal laws necessary to motivate savings and labor, but rather privileged access to property and the imperatives of labor motivation under alienating work regimes.

A social theory of human nature emphasizes that the dichotomy between decision makers and decision takers leaves the worker with virtually no control over what will be produced, how it will be produced, and little sense of contributing useful goods or services to the community. The separation of owners-managers from workers, of mental from manual, relegates the individual worker to mindless tasks, crushing the opportunity to develop her/his human capacities to reflect, design, invent, and to relate interpersonally in emotionally complex but self-conscious ways. In short, the inherent fragmentation, isolation, and instrumentality of work dehumanize social relationships. The motivation of labor under such arrangements does require individual and external incentives which stand outside the labor process.

Until income distribution analyses emphasize such ties between worklife arrangements and incentive systems, they will be specific in nature and fundamentally conservative in implication. The move toward equality will require a broader blend of external, individual, internal, and social incentives. Democratizing worklife, by breaking down the divisions between manual and mental, makes jobs more fulfilling as ends in themselves. In this way, worker participation in decision making reduces the need for external incentives. Similarly workers who have gained a stake in the production process and in the community have reason to shift from passive conformist attitudes to motivated agents sharing in the task of expanding production. Worker participation in the design of production, besides reducing the burden placed on external and individual incentives, enhances the inventive capacities of workers and thereby worker productivity.

Seen from this perspective, it is little wonder that systems which relegate workers to mindless tasks require coercion, such as the threat of impoverishment to extract labor effort. It also helps to explain the progress of China and Cuba. Both have broken down traditional market oriented divisions of labor and integrated workers into decision-making capacities. Both have motivated enormous labor effort by creating an institutional context of direct worker participation in plant organization and by fostering a social environment of interdependence and reciprocity as opposed to atomization and individualism.

Clearly the democratization of worklife

will also require production for use. Workers must have a say in determining what will be produced if social incentives are to be meaningful. Once more, moves toward workplace democratization will be strongly resisted by private owners for, to them, a worker capable of designing production alternatives is potentially capable not only of competition within the prevailing economic order but of designing an alternative economic order.

These reforms go beyond technical adjustments in governmental policies; they point to changes in the relationships of production and the ideology of individualism. The latter is itself a product of institutional arrangements that preclude collective social action. For the underclass it is an ideology of frustration and impotence which leads victims to blame themselves for social injustices and to perceive the prevailing order as immutable and the existing conditions as hopeless.

Obviously, alterations in the purpose and process of production and in the sustaining ideology will require a social movement to secure implementation and will be resisted with all the power at the disposal of the dominant class. But the political obstacles to breaking with the traditional division of labor are not in themselves an argument against our interpretation of inequality or our proposals for change as much as an argument against the system which obstructs such programs.

A final note. The deep-seated nature of social change required to move the world economy toward greater equality can elicit a sense of pessimism. It shouldn't. The task of science is to make transparent the critical forces that are not obvious, to expose the underlying structural relationships. Once the forces producing inequality, for example, are made evident it is clear that the barriers to creating a better world are not imposed by nature, but are social problems subject to social action. The potential offered by rational, informed, collective social action will not be realized without struggle. That struggle must be informed by a proper identification of the real barriers to a more equitable world order.

# INTERNATIONAL INTERDEPENDENCE: IMPLICATIONS FOR POLICY

# Trade and Employment Effects in the United States of Multilateral Tariff Reductions

By ROBERT E. BALDWIN*

This paper summarizes certain aspects of my research into the trade and employment effects in the United States of a significant multilateral reduction in trade-distorting measures by the world's major trading nations. The study differs from earlier investigations into this question such as those by Giorgio Basevi (1968), Stephen Magee (1973), Robert Stern (1964), and Beatrice Vaccara and Walter Salant (1960) in that the industry breakdown is much more detailed and the consequences of a multilateral tariff reduction on both *U.S.* export and import-competing industries is taken into account. By estimating not only the net trade and employment effects of a significant tariff reduction in over 350 industries but also in the 50 states and on some 14 occupational groups, it is hoped that the results will be useful for those who are now embarked on the so-called Tokyo round of trade negotiations within the framework of the General Agreement of Tariffs and Trade (*GATT*). Another novel feature of the study is the estimation of the net employment effects of multilateral tariff cuts under the assumption of flexible exchange rates.

## I. Analytical Framework

A key assumption of the analytical framework used in the study is that imports are imperfect substitutes for domestic production. The usual perfect substitution model may be adequate for dealing with agricultural products and raw materials, but it gives inconsistent results when empirical estimates of elasticities of import demand, domestic demand, and domestic supply are compared with the theoretical relationships among these variables that must hold in a perfect substitution model.[1] A more appropriate model for trade in manufactures is one in which imports and domestic production are imperfect substitutes and supply curves for each of these types of goods are infinitely elastic. The assumption of an infinite supply elasticity of imports is traditional in trade theory,[2] while the

[1] If domestic and import products are perfect substitutes then $e_m=(1+O_s/O_m)e_d+(O_s/O_m)e_s$, where $e_m$, $e_d$, $e_s$ are, respectively, the elasticities of import demand, domestic demand, and domestic supply and $O_s$ and $O_m$ are the levels of domestic output and imports, respectively. However, for most manufactured products, when empirical estimates of $e_m$ and $e_d$ are combined with actual $O_s/O_m$ ratios, the implied $e_s$ ratio associated with these figures is much smaller than the very high values of $e_s$ obtained from direct empirical estimation.

[2] Although an infinite import supply curve is generally assumed, recent evidence seems to indicate that it is upward sloping for the United States. For example, Peter Clark, "The Effects of Recent Exchange Rate Changes on *U.S.* Trade Balance," Treasury Conference, April 1974, found that a 1 percent decrease in the *U.S.* demand for finished manufactures caused foreign producers to reduce their prices by .32 percent. He also found that as foreign demand for *U.S.* exports increased, there was no change in the dollar price of *U.S.* exports.

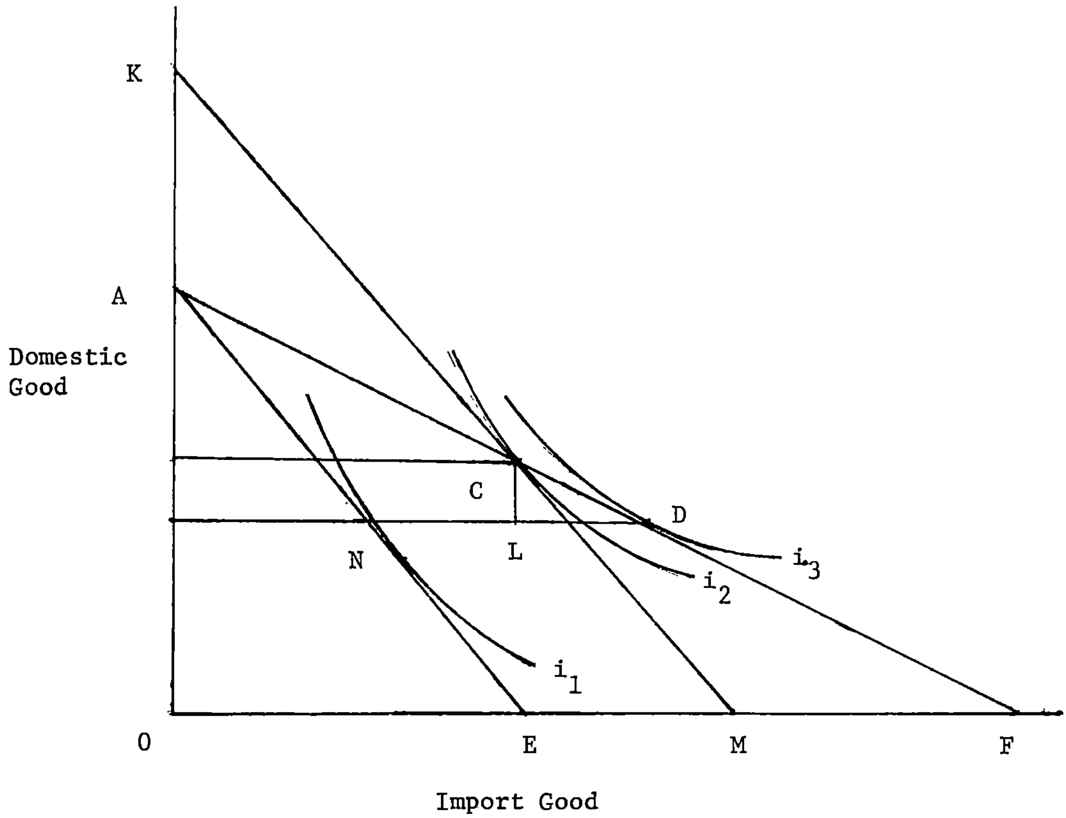

FIGURE 1

infinite supply elasticity for domestic production of manufactured goods is widely supported by empirical estimation, e.g., A. Walters (1963).[3]

Another simplifying assumption made in the analysis is that the compensated cross-price elasticity of demand is zero between any import good and all other goods except for the domestic substitute for this import good. Moreover, as is customary in tariff analysis in order to eliminate any macro effects, it is assumed that total government expenditures and tax revenues remain unchanged. Consequently, if government expenditures are unchanged, as will be assumed here, and import duties are changed, it is assumed that income taxes are changed in such a way as to hold total tax revenue unchanged.

These points can be better understood with the aid of Figure 1 in which a simple exchange situation is depicted. Let $OA$ be the country's supply of the domestic good, the slopes of $AE$ and $AF$ reflect the domestic price and the fixed international price, respectively, of the import good, and $i_1$, $i_2$ and $i_3$ be three community indifference curves. Postulating that consumers are identical in every respect, the point $N$ indicates the optimal combination of the domestic and import goods if a duty is imposed without any offsetting change in either taxes or government spending. However, if income taxes are also reduced at the same time by a sum equal to the increased tariff revenues measured in terms of the domestic good

[3] In later work a less than infinite elasticity of domestic supply will be used for agricultural and mineral products, but at this stage the infinite elasticity assumption is employed for these products, too.

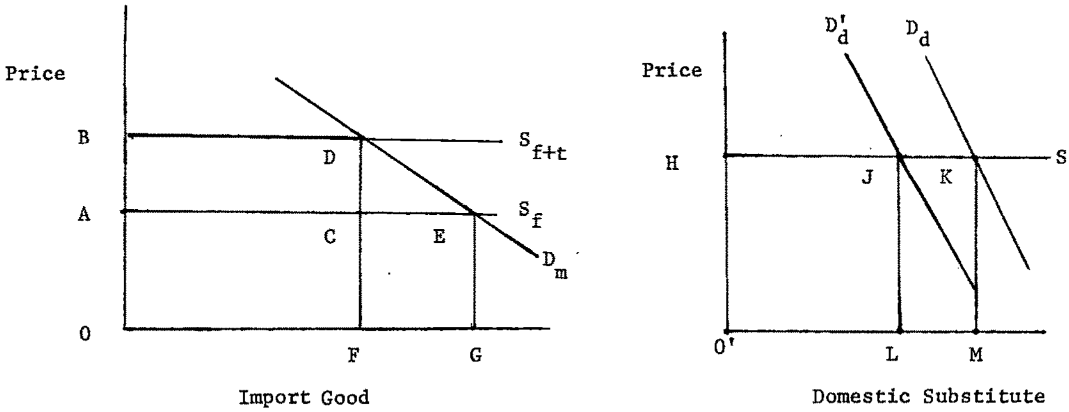

FIGURE 2

($AK$ equals both the tariff proceeds and the additional disposal income due to the cut in the income tax), consumers divide the additional income between the two goods in such a way that the point $C$ is reached. Consequently, to take the opposite case where the tariff on the import good is removed and the income tax is increased at the same time, consumers trade from the point $A$ along the line $AF$ until the point $D$ is reached.

Since the line $AF$ passes through $C$, consumers are able to purchase the same quantities of these two goods. In other words, apparent real income remains the same. Although consumers do not wish to substitute the import good for third goods, they do wish to purchase more of the import good and less of its domestic substitute. This substitution effect from $C$ to $D$ in Figure 1 indicates the increase in actual real income in the move to free trade conditions.

A representation of these relationships using ordinary demand and supply curves is shown in Figure 2.[4] In the figure, $D_m$ and $D_d$ are income-compensated demand curves; $S_f$ and $S_{ft}$ are the foreign supply of imports without and with, respectively, the import tax; and $S_d$ is the domestic supply curve of the import substitute. The area $ABDC$ is equal to the tariff proceeds as well as the decrease in the income tax and corresponds to $AK$ (or $EM$) in Figure 1. When the duty is eliminated and the sum paid to foreign producers increases by $FCEG$ (equals $LC$ in Figure 1), domestic expenditures on the local substitute decline by an equal sum, namely, $LJKM$ in Figure 2 or $LC$ in Figure 1.

## II. Data Sources

The trade and tariff data needed for the study are available for 1970 and 1971 from the secretariat of $GATT$. This organization obtained tariff and trade information on a tariff-line basis from its major trading members and then classified it according to the Brussels Trade Nomenclature ($BTN$) at a 4-digit level.[5] The industry breakdown employed corresponds to the 367-sector delineation of the 1967 sector input-output table prepared by the U.S. Department of Commerce. Intermediate-use coefficients from this study were also employed.

Five additional sets of data are utilized in estimating the trade-balance impact of multilateral duty reductions and then the

[4] One difference is that domestic production of the domestic good is permitted to vary.

[5] The countries covered are: the United States, Japan, Canada, Austria, New Zealand, Finland, Switzerland, Sweden, Australia, Norway and the nine European Community ($EC$) members, namely, France, Germany, Italy, Belgium, Luxembourg, Denmark, the United Kingdom, and Ireland.

employment changes associated with these trade effects. They are: import and export demand and supply elasticities for the 310 trading industries in the 367 input-output table; employment coefficients classified on the same industry basis; a breakdown of employment in each industry by skill groups, a breakdown of employment in each industry by state; and finally a set of price deflators to put the 1971 trade figures on a comparable basis with the 1967 input-output and labor-output coefficients used in the study.

Trade and employment effects were calculated using five alternative sets of import and export of demand elasticities.[6] The preferred set (Set I) is based on the import and export demand elasticities calculated by Margaret Buckler and Clopper Almon (1972) for some 75 manufactured goods and import demand elasticities calculated by Stephen Magee (1970) for crude foodstuffs, crude materials and manufactured food. Another set (Set II) consists of the Buckler-Almon elasticities modified by estimates for 20 industries calculated by the staff of the International Trade Commission. The remaining three elasticity sets consist of a fourfold grouping of one-digit Standard International Trade Classes and are based on a survey of the literature on trade elasticities by Robert Stern (1975). One set is termed the "best" by Stern; another set (Set IV) is made up of import demand estimates of previous investigators that are on the low side and export demand elasticities on the high side; and a final set (Set V) consists of high import and low export elasticities.

[6] The desired but unavailable (in the required detail) elasticity data are import demand elasticities for each participating country. Rather than use *U.S.* import demand elasticities for all countries, *U.S.* export demand elasticities are utilized, since the aggregative results are substantially the same and the different competitive position of an industry on the import versus the export side is taken into account.

Labor coefficients for the 367 sectors of the 1967 input-output table were kindly supplied by Clark Bullard of the University of Illinois.[7] A breakdown of the labor coefficients into 14 different skill groupings was supplied by the *BLS,* while sector employment by state was obtained from the 1970 Sample Census of Population.[8] Finally, in order to express 1971 trade figures in terms of the 1967 prices used for the input-output and labor coefficients, exports and imports classified into a 4-digit level of the Standard Industrial Classification (*SIC*) were deflated by 4-digit unit values obtained from the Bureau of Economic Analysis of the U.S. Department of Commerce. After this deflation the trade figures were then classified on the basis of the 367 sectors of the 1967 input-output table.

### III. Estimates of the Trade and Employment Effects of Tariff Reductions

The aggregate trade and employment effects in the United States of a 50 percent, multilateral tariff reduction are presented in Table 1. The Buckler-Almon-Magee elasticities are utilized in calculating these effects. In addition, certain products have been excluded from the tariff-cutting process, namely, *U.S.* exports to the European community (*EC*) of agricultural products subject to quantitative restrictions in this country, all *U.S.* exports and imports of textiles covered by the international textile agreement, and *U.S.* imports of oil. All of these commodities are subject to nontariff barriers

[7] Some modifications in these coefficients were made after consulting with the Bureau of Labor Statistics (*BLS*) in the U.S. Department of Labor. The figures also are average rather than marginal labor coefficients. However, if short-run supply curves are in fact horizontal, there will be no difference in these two types of coefficients.

[8] Employment by state is divided into only 19 industries.

TABLE 1—EFFECTS ON U.S. TRADE AND EMPLOYMENT ON A 50 PERCENT LINEAR TARIFF REDUCTION

| | All Industries | Manufacturing |
|---|---|---|
| Change in exports (millions of $) | 1,750 | 1,591 |
| Change in imports (millions of $) | 1,746 | 1,717 |
| Net trade change (millions of $) | 4 | −126 |
| Export-related employment change (man-years) | +136,000 | 116,400 |
| Import-related employment change (man-years) | −151,200 | −148,100 |
| Net change in employment (man-years) | − 15,200 | − 31,700 |

that operate independently of tariffs. Cutting duties on these items will not increase trade.

While a 50 percent duty reduction leads to changes in exports and imports that each exceed $1.5 billion, the net trade change is a negligible $+4 million, for all industries and $–126 million for manufacturing alone. The net employment impact is also small: –15,200 man-years for all industries and –31,700 man-years for manufacturing.

As previously noted, estimates of trade and employment effects from a 50 percent tariff cut were made with four other elasticity sets. Table 2 gives these results. Unless one combines import demand elasticities taken from the high side of the range of such figures that various investigators have found together with export demand elasticities taken from the low side of the range of estimates for these elasticities, i.e., Set V, the figures in Table 2 show that aggregative trade and employment effects of a 50 percent reduction of tariffs are small or moderately favorable. The remainder of the results reported in this paper are based on the Buckler-Almon-Magee elasticity estimates, i.e., Set I.

Some indication of the distribution effects of tariff reductions can be obtained by breaking down aggregate employment changes into various skill groups. Dividing net employment changes into fourteen occupational classes yields the following percentage changes in labor requirements: research and development workers at + .14; professional and technical workers (production related) +.08; other professional and technical workers 0; management and administrative employees (production related) –.03; other management and administrative employees 0; craftsmen –.05; sales workers –.03; clerical workers –.02; operatives –.14; laborers (except farm) –.08; service workers –.01; private household workers 0; and farm laborers

TABLE 2—AGGREGATE U.S. TRADE AND EMPLOYMENT EFFECTS OF A 50 PERCENT TARIFF CUT UNDER VARIOUS TRADE ELASTICITIES

| | Set I | Set II | Set III | Set IV | Set V |
|---|---|---|---|---|---|
| Net trade effect | | | | | |
| (in millions of $) | | | | | |
| All industries | 4 | 161 | −310 | 1,493 | −2,932 |
| Manufacturing | −126 | 31 | −343 | 1,328 | −2,834 |
| Net employment effect | | | | | |
| (in man years) | | | | | |
| All industries | −15,200 | 900 | −37,300 | 113,300 | −266,400 |
| Manufacturing | −31,700 | −15,600 | −40,900 | 93,100 | −251,200 |

and foremen +.45. These figures confirm once again that the basis of the *U.S.* comparative advantage rests on the existence of a relatively abundant supply of research and development workers (who give the United States a technological jump on other countries), other professional workers, and agricultural resources. The demands for other skill groups decline somewhat with the reduction being the largest for semi-skilled (operatives) and nonfarm laborers.

While overall trade and employment effects of a 50 percent tariff cut are small under the most likely sets of trade elasticities, this does not mean that no industry is significantly harmed or benefited from the duty reductions. If one-half of one percent of an industry's labor force is arbitrarily chosen to divide industries that are or are not significantly effected, the list of industries in which there are employment changes of one-half of one percent or more consists of 54 import-sensitive industries and 19 export-oriented industries. The employment change for the import sensitive industries is 48,000 and for the export-oriented industries, 34,000.

In considering whether to phase cuts in import-sensitive industries over the full ten years permitted by the Trade Act of 1974, an initial consideration might be whether the annual growth rate for labor in an industry more than offsets the labor force decline associated with a ten-year phasing arrangement. If it did, there would be no reason for not reducing duties in the industry by the full 50 percent. If average annual growth rates for labor that prevailed from 1958–71 are representative of the next ten years, the growth factor eliminates unemployment problems caused by the tariff reductions in 34 of the 54 import sensitive industries. The remaining 20 consist of such industries as lace goods, tire cord fabric, cordage and twine, industrial leather, nonrubber footware, glass products, pottery products, lead and zinc, textile machinery, electronic tubes, and artificial flowers.

Industries that benefit in employment terms by one-half or more percent include: paperboard mills, computing machines, electrical measuring instruments, semiconductors, aircrafts and aircraft equipment, and scientific instruments.

The regional distribution is also of interest to trade negotiators, and therefore a state by state employment impact of a 50 percent duty reduction has been estimated. The 50 percent multilateral tariff reduction brings about an employment decline in 34 of the 50 states. However, these losses are very small. For example, the states in which labor requirements fall by more than 1000 man-years are Illinois, Massachusetts, Michigan, New York, and Pennsylvania. In relative terms, employment losses are the highest in four New England states—Massachusetts, Maine, New Hampshire, and Rhode Island, whereas the relative employment gains are the greatest in Kansas, Minnesota, North Dakota, and South Dakota.

All of the previously reported results are based upon a fixed exchange-rate model. However, it is possible to estimate the exchange-rate change required on the part of the United States to eliminate any deficit or surplus pressures on the trade balance as a result of tariff cuts. For elasticity Sets I-III, the required percentage exchange-rate changes needed for a 50 percent tariff cut on all industries are within a range of +.003 and –.688. The extreme elasticity assumptions used in Sets IV and V yield +2.43 and –2.46, respectively. There are still, of course, labor demand effects even though there is no trade-balance impact. These changes are, however, small for all elasticity sets.

## IV. Conclusions

The main conclusion emerging from the study is that the United States can participate in a substantial tariff-cutting negotiation without causing significant adverse trade and employment effects in the country. Even without taking into account exchange-rate changes, any adverse trade and employment effects are small except under one extreme set of trade elasticities. When exchange rate variations are taken into account, net aggregate trade changes are eliminated and total employment shifts become minimal even under the most adverse elasticity assumptions.

Not only are aggregate economic effects of a significant tariff-cutting exercise small, but the effects on individual industries, on various occupational groups, and on employment in different states are minimal in most cases. For example, as previously noted, normal industry growth can handle any adverse employment impact, in all but 20 industries, if the reductions are staged over a ten-year period. Employment changes both by skill group and by state are insignificant, especially if the cuts are staged over a ten-year period.

# American Multinationals and the U.S. Economy

By THOMAS HORST*

The impact of American multinational firms on the United States economy and its foreign relations is the subject of a study, *American Multinationals and American Interests*, which Fred Bergsten, Theodore Moran and I have recently completed for the Brookings Institution. If condensing two years of work by three authors into one book was difficult, summarizing my contribution here is all but impossible. But assuming that the effort would generate more interest than a careful dissection of the foreign tax credit, let me describe our more important findings in the areas of international trade, income taxes, and antitrust.

## I. Trade Issues

The impact of American investments abroad on *U.S.* exports and imports is certainly a controversial issue. Whatever interest it may hold in its own right is overshadowed by its implications for the export of American jobs, the distribution of income between American labor and capital, and the balance of payments. In approaching this complex issue, we focused on the microeconomics of foreign trade and investment rather than on the general-equilibrium linkages. An American multinational chooses—explicitly or implicitly—whether to supply its foreign and domestic markets with goods manufactured at home or overseas. When a company like International Business Machines (*IBM*) decides to manufacture its computers for its European customers in Europe, it displaces *its own* exports of computers from the United States. While data on the exports, imports and foreign affiliate sales of individual American investors are exceedingly hard to come by, industry statistics are comparatively easy to find and seemed altogether appropriate for demonstrating the substitution of subsidiary production for American exports.

While this notion of direct substitution has obvious intuitive appeal and is implicit in the labor unions' charges that American investors export their jobs, we had no success whatsoever in demonstrating statistically that it was a major factor in shaping the flows of *U.S.* exports and imports. If one industry's exports and foreign subsidiary sales are compared to another's, one often finds that the industry which exports more also produces more overseas. This simple correlation does not imply, however, that exporting stimulates foreign production or vice versa. Often one industry is more technically sophisticated than the other, and its technical capability assists its exports *and* its foreign production. What surprised us was that when we used common statistical procedures to correct for differences in technical sophistication and other spurious factors, we still could not demonstrate any clear or obvious tradeoff between exporting and foreign subsidiary production. There was no evidence that an increase in foreign subsidiary production was normally accompanied by a reduction in *U.S.* exports or, for that matter, an increase in *U.S.* imports. In fact, there was some evidence that a *modest* amount

* The Fletcher School of Law and Diplomacy, Tufts University.

of foreign investment might be prerequisite to exporting. But ignoring that and focusing on the industries with substantial exports or overseas markets, we found no statistically significant relationship across industries between foreign investing and *U.S.* exports or imports.

What conclusion should we draw from the absence of any such relationship? That our exports are never displaced or our imports never enhanced by foreign production? That tariffs, transport costs, international differences in labor costs and exchange rates have no impact on the location of a multinational's production? Most certainly not. But our negative findings do suggest that the implications of subsidiary production for *U.S.* exports or imports have been overstated and/or that the ways in which foreign affiliate production may complement *U.S.* exports have been underestimated. Although economists often ignore the sort of market imperfections on which the complementarity may be based, the histories of multinational corporations or industries are more revealing. When American firms invest abroad, they not only produce goods which hypothetically might be produced in the United States, but they also undertake a wide variety of nonmanufacturing activities to expand the foreign market for their products. Direct selling, advertising, wholesale and even retail distribution, adapting American products to local market conditions, follow-up maintenance and repair all play an indispensible role in broadening the market for the firm's products. In labeling these activities "ancillary" when they are performed by an American manufacturer, it has been all too easy to ignore their significance.

Our conclusions are simple. Published foreign investment statistics reflect a heterogeneous combination of manufacturing and nonmanufacturing activities, and while the foreign *manufacturing* may be an alternative to American production, the *nonmanufacturing* activities tend to promote *U.S.* exports by expanding the market for *U.S.* goods. We would not risk belaboring this point were it not for the regretable tendency of such distinctions to be the first casualties of public policy debates over foreign investment. The Burke-Hartke Bill, which was supported by the *AFL-CIO* and finally rejected in 1973 by the Congress after a long and bitter debate, proposed to repeal the foreign tax credit for *all* foreign investment. By subjecting foreign investment income to double taxation, the labor unions hoped to slow down or reverse the export of jobs. We conclude that such a policy in failing to discriminate between one type of foreign investment and another could easily do more harm than good to the U.S. trade balance. The depreciation of the U.S. dollar did far more to reverse the export of jobs than the Burke-Hartke Bill ever could have.

## II. Tax Issues

Under current United States tax policy, foreign investment income is subject to the corporate income tax, but not until that income is formally paid as a dividend to the American investor, and then a tax credit is given for foreign income taxes. Even if this policy has had an ambiguous impact on *U.S.* exports and imports, it has had two unfortunate side effects. It has allowed foreign governments to collect the lion's share of taxes on foreign investment income, a phenomenon which is highly significant in any reckoning of the national gains from international investment. Secondly, it has encouraged American investors to undercharge their foreign affiliates for intra-company exports and for mutually beneficial research and development programs and other joint expenses. In the end the United States has

TABLE 1—ESTIMATED IMPACT OF ELIMINATING DEFERRAL FOR MANUFACTURING FIRMS, 1974
(Millions of dollars)

| Variable Affected | Impact Assuming No Change in Intra-Firm Financial Practices | Estimated 1974 Value | Percentage Change |
|---|---|---|---|
| Total Domestic Assets | 2,436 | 338,400 | .7% |
| Total Foreign Assets | −3,216 | 140,400 | −2.2% |
| Intra-firm Financial Transfer | −11,046 | 28,080 | −39.3% |
| Consolidated After-Tax Earnings | −755 | 43,123 | −1.8% |
| *U.S.* Income Taxes[a] | 1,233 | 28,815 | 4.2% |
| Foreign Income & Withholding Taxes | −433 | 9,569 | −4.5% |

[a] *U.S.* income taxes include taxes paid on parents' domestic income.

little or no share in the taxes paid on the income generated by American investments abroad and may even lose some tax revenues on domestic income to overseas governments.

As an aid in evaluating various tax reforms, we have constructed a microeconomic model of a multinational firm and used various estimates of the model's parameters to simulate the multinational's response to possible changes in United States tax policy. In Table 1 we show our estimates of the impact of eliminating deferral for manufacturing investors in 1974. Without the deferral of foreign investment income, we estimate that the total assets of foreign manufacturing affiliates would be reduced by $3.2 billion, which is 2.3 percent of their estimated total value. The total domestic assets of the multinationals might rise by $2.4 billion, which is only 0.7 percent of these firms' domestic assets. That domestic investment rises by less than foreign investment falls reflects the loss of investable funds through higher tax payments to the U.S. Treasury. The primary reason why eliminating deferral has so small an impact on foreign and domestic investment is that foreign governments collect income and withholding taxes amounting to 45 percent of foreign investment income. If deferral were repealed, the total taxes imposed on foreign investment income would not exceed 48 percent, the statutory *U.S.* tax rate. If repealing deferral adds only 3 percent to the total taxes on foreign investment income, the impact on the location of investment is apt to be small.

But this is not to say that the United States has little to gain by eliminating deferral. Far from it. We estimate that the total taxes paid by American investors to the U.S. Treasury (including taxes on domestic income) would rise by $1.2 billion, a 4.2 percent increase in those taxes. Eliminating deferral has a comparatively larger impact on U.S. taxable income and tax payments than on domestic investment (a 4.2 percent gain versus a 0.7 percent gain). This striking difference reflects our presumption that the elimination of deferral would encourage American investors to finance more of their overseas investment with locally borrowed funds than they now do. If the subsidiaries borrow in local capital markets, the interest is deductible from their taxable income and not from their American parents' domestic income. The gains from encouraging American investors to refinance their foreign operations constitute a major incentive to repeal deferral.

The tax gains of this particular reform do not end here. Deferral encourages firms to undercharge their foreign affiliates for research and development programs undertaken in the United States. Although American investors often spend as much as 5 percent of their domestic sales receipts on research and development programs, only a small portion of the total cost is charged back to the foreign affiliates. In 1973, for example, total royalties, management fees, rentals and all other such charges amounted to only 1.1 percent of manufacturing affiliates' sales. If repealing deferral encouraged firms to raise these charges by another 1.1 percent, the tax gain for the United States in 1974 would have been almost $1 billion—a gain over and above that shown in Table 1.

So while we favor the repeal of deferral, we believe that the primary benefits are quite different from those stressed by earlier writers. The principal gain derives from the tax benefits of encouraging American investors to alter the capital structure of their overseas affiliates and to increase the portion of taxable income allocated to the *U.S.* parent. The more familiar gains—the more efficient pattern of international investment and the additional *U.S.* taxes collected on subsidiaries retained earnings—may pale by comparison.

### III. Antitrust Issues

As Stephen Hymer, Raymond Vernon, Richard Caves, and several other authors have noted, American multinationals are anything but the atomistic competitors envisaged by classical economic analysts. Multinational firms tend, if anything, to be the largest firms in their industries, and those industries are distinguished by high advertising, high research and development spending, substantial economies of scale and other wellsprings of monopoly power. The primary connection between multinationalization and monopolization is simple: the technological and marketing advantages which allow a few firms to dominate the market also serve as a springboard for entering foreign markets.

Our interest was not in reconfirming this primary linkage between foreign investment and market power, but in determining whether foreign investment reinforces or entrenches the multinationals' market position in the United States. Our suspicions were aroused not by the opportunities a multinational may have to use its foreign earnings to finance predatory attacks on its domestic competitors (as Richard J. Barnet and Ronald E. Müller argued in *Global Reach*), but by the possibility that the underlying sources of market power—patents, brand differentiation, vertical integration—would be augmented by foreign investment.

A prima facie case for this hypothesis is easy enough to make—the multinational companies themselves often claim that only through their large, global operations can they afford the substantial research and development programs they undertake. The fruits of their research efforts help them fend off foreign competition when they enter foreign markets while enhancing their premier positions in the United States.

Whether the contribution of foreign investment to domestic market power is large or small is a much harder question to answer. We have examined Internal Revenue Service statistics on the domestic rates of return for firms of different sizes and in different industries. Industrial organization analysts reason that firms will be able to earn consistently higher profits than average only if they are protected in one way or another from new competition. A summary of our findings appears in Table 2 where we have cross-tabulated firms' domestic returns on capital according to whether they were

"multinational" or "domestic," whether they spent heavily on advertising or not, whether they employed many scientists and engineers or not, and whether they were large or small. Comparisons are made for 1966, a good year, and 1970, a bad one. By reading up and down the columns, one can see that firms spending heavily on advertising consistently showed higher rates of return than firms which advertise less. The advantages of technological effort are less striking, but apparent nonetheless. Large firms do not, however, consistently earn more than small firms do.

TABLE 2—CROSS TABULATIONS OF DOMESTIC RETURNS AS A PERCENT OF PARENTS' TOTAL ASSETS, 1966 AND 1970

| | Multinational Groups | Domestic Groups |
|---|---|---|
| *1966* | | |
| High Advertising | 17.0% | 13.8% |
| Low Advertising | 13.0% | 11.4% |
| *1970* | | |
| High Advertising | 14.3% | 10.8% |
| Low Advertising | 8.1% | 6.6% |
| *1966* | | |
| High Technology | 16.7% | 13.2% |
| Low Technology | 12.6% | 11.5% |
| *1970* | | |
| High Technology | 11.0% | 5.7% |
| Low Technology | 8.7% | 7.1% |
| *1966* | | |
| Large Firms | 14.9% | 11.6% |
| Small Firms | 13.8% | 11.7% |
| *1970* | | |
| Large Firms | 9.7% | 6.2% |
| Small Firms | 9.6% | 7.3% |

*Note:* Domestic Net Returns equal net income before taxes plus interest paid on debt less foreign dividends and tax credits. Multinationals were those industry-size-class groups whose foreign dividends and tax credits exceeded 1 percent of parents' assets; high advertisers were those groups spending amounts more than 5 percent of parents' assets on advertising; high technology *industries* were those whose 1970 employment of scientists and engineers exceeded 5 percent of their total employment; large firms had more than $250 million in total assets. The "groups" of American corporations consisted of all firms of a given size class (e.g., $50-$100 million in total assets) in one of seventy-five "minor" industries (e.g., meatpacking). The source of these statistics is the Internal Revenue Service, *Sourcebook of Statistics of Income, Corporations, 1966* and *1970*, obtained from the National Archives in machine-readable form.

The more interesting relationship, so far as we are concerned is apparent in reading across the rows. Now we are comparing firms spending comparable amounts on advertising, employing comparable numbers of scientists and engineers, or of comparable size to determine whether those with foreign operations earn higher returns on their *domestic* investments than those without overseas investments. What is striking about these horizontal comparisons is that for high advertisers and low, large and small employers of scientists and engineers, and large firms and small, *the multinational groups earned significantly higher domestic returns than domestic groups in 1966 and 1970.* (The relationship also held for each of the seven years 1965–71.) The possibility that foreign investment significantly increases the domestic monopoly power of multinational firms clearly should not be dismissed out of hand.

Unfortunately, this sort of monopoly power hits American antitrust policy right where it is weakest. Antitrust policy has had its greatest successes in undoing price-fixing and market-sharing arrangements among would-be cartels and in preventing horizontal and vertical mergers among large firms. Its greatest failures have come in attacking market power inherent in economies of scale, technological knowhow and other basic elements of industry structure. These failures may be due in part to a lack of legal resources or political support for antitrust prosecution of large firms, but are also a reflection of a troublesome tradeoff between competition and economic efficiency. Even if the Justice Department or the Federal Trade Commission can prove that a technologically advanced firm has illegally monopolized a market, judges are often reluctant to split the company into several

smaller, independent competitors for fear of sacrificing substantial economies of scale the firm achieves in production or in developing new technology. Foreign investment tends to reinforce domestic market power in those very cases where antitrust authorities are least willing and able to act.

Every cloud has its silver lining, and this one is no exception. In trying to find an effective remedy for this type of monopoly power, antitrust authorities often look for natural ways to split dominant firms into self-sufficient entities, just as a jeweler looks for a natural way to split a diamond. In this search we would hope that antitrust authorities would not overlook the obvious opportunities to split the large and more sufficient foreign subsidiaries from their American parents. Although these subsidiaries are not current participants in *U.S.* product markets, they are often credible entrants. Is *IBM* Europe not a credible contender in the *U.S.* computer industry? Is General Motors, Canada not a potential entrant in the United States auto industry? In fairness to the American parent, we presume that it would be allowed to compete with its erstwhile affiliates in overseas markets, just as they would compete with their erstwhile parents in the domestic *U.S.* markets. In ordering the cross-licensing of critical patents and otherwise fashioning an effective remedy, the objective should always be to promote competition, not to emasculate one national firm or the other. Multinationals may thus derive competitive advantages over their domestic competition from their foreign operations, but those foreign operations may be a solution to, and not just a cause of, the problem of market power.

# Increasing International Economic Interdependence: the Implications for Research

*By* C. Fred Bergsten and William R. Cline*

Increasing economic interdependence can perhaps best be defined as a growing impact of external events on national economies. One of its major implications for research is that all national economic models must be opened to encompass meaningfully the foreign sector.

Economists in most countries have opened their models long ago, but most American economists have not. Yet the share of exports in the *U.S.* economy has doubled in the last fifteen years, and the share of imports has doubled in just seven years. These *U.S.* ratios (about 7 percent, and still rising rapidly) are now only slightly below the same ratios in Japan and the European Common Market as a group (about 9 percent, and fairly stable).

In addition, about one-third of the profits of *U.S.* corporations now derive from overseas activities, primarily their foreign direct investments. If these profits are taken into account along with trade, the *U.S.* economy has probably become more open than Japan or Western Europe (as a unit) in quantitative terms. Even the absolute numbers are impressive: the *U.S.* trade balance, excluding the effects of the rise in oil prices, strengthened by at least $35 billion from 1972 through 1975—without which our gross national product would have been over two percentage points lower.

This openness has become critically important for *U.S.* economic policy. The overvaluation of the dollar was adding almost one full percentage point to the *U.S.* unemployment rate in 1971. External factors accounted for one-quarter to one-half of the rise in the rate of inflation from 1972 through 1974 (Richard Berner, Peter Clark, J. Enzler and Barbara Lowrey). The United States can no longer export its internal inflation through the operation of a dollar-based system of fixed exchange rates as it did to a significant degree in the late 1960's (Bergsten 1976).

Oil and food are only the most obvious examples of external shocks to particular *U.S.* economic sectors. About 20 percent of *U.S.* industrial production and over one-third of *U.S.* farm output are exported. The United States already imports more than 50 percent of its needs of nine of the thirteen key industrial raw materials. Closed models can no longer accurately depict or forecast the *U.S.* economy at either the macroeconomic or sectoral levels.

## I. The Effects of Foreign Economic Policy Instruments

This increasing openness of national economies has increased the importance of the instruments of foreign economic policy, as countries seek both to fend off negative effects of outside events and to harness such events to their positive objectives. New research is needed on a variety of aspects of these instruments.

Countries have traditionally sought to export unemployment to their neighbors through exchange-rate depreciations, ex-

* The Brookings Institution.

port subsidies and import controls. But in 1973–74, as inflation superseded unemployment as the primary internal problem in most countries, there were widespread efforts to export inflation through opposite types of external economic policy—exchange-rate *appreciations, export* controls, and unilateral import *liberalization*. For example, several countries (including Austria, Germany and Norway) revalued their exchange rates though they were not running payments surpluses and Japan spent at least $5 billion to keep the yen from depreciating, just a few years after many of the same countries had bitterly resisted massive international pressure for similar steps when they were running huge surpluses. Numerous countries (including some of the most protectionist such as Australia, Canada and Japan) cut their tariffs across the board, and many others (including the United States on such politically sensitive items as sugar and meat) eliminated import quotas. Both industrialized and developing countries invoked export controls across a wide range of primary and manufactured products (Bergsten 1974).

If inflation once more becomes the chief internal concern of most countries, these efforts to use external policy to export it may again become major sources of international conflict. Alternatively, in a world of continued stagflation, we could expect national efforts to export simultaneously both inflation and unemployment (in different sectors, as with the recent *U.S.* controls on food exports and steel imports).

These developments raise major issues for economic analysis. One is the need for empirical evidence on the external corollary of the Phillips curve: How much inflation (unemployment) must be accepted as the price for reducing unemployment (inflation) through a devaluation (appreciation) of the exchange rate or imposition (liberalization) of import controls? Protectionist pressures have been restrained throughout the recent recession largely by fears of their simultaneous inflationary consequences, but economists have done little to define the issue rigorously and hence lay a foundation for sensible policy choices.

Tests are also needed of the effectiveness of these policy instruments in meeting their proclaimed objectives. For example, export controls reduce internal inflation by increasing domestic supply of the controlled product. But they may add to inflation in the short run by weakening the exchange rate. They may also be inflationary in the long run by dampening the elasticity of domestic supply; on the other hand, they may trigger increased supply in other areas as consuming countries seek to diversify their sources. They may encourage the adoption of export controls by other countries. Policy makers have little intellectual basis for addressing such issues, which are now arising with great frequency due to the acceleration of internal economic interdependence.

## II. Flexible Exchange Rates

International monetary arrangements stand at the center of the increasingly interdependent world economy, and have undergone dramatic structural change in recent years. The present international monetary system is extremely heterogeneous. Most countries retain fixed exchange rates. But the minority of countries whose exchange rates are floating account for over seventy percent of world trade. Data will be emerging over the next few years which will make possible analyses of several key issues regarding the effects and desirability of alternative monetary regimes, and a comparison with earlier periods in which fixity or flexibility dominated.

A major issue is the effectiveness of more flexible exchange rates in achieving balance-of-payments adjustment. The effects seem clearly positive for the United States and Japan, but less so for Germany and Britain. Country studies rank high on the research agenda.

So do studies of the systemic impact of more flexible rates. Some observers claim that exchange-rate changes can only raise world prices and do nothing to eliminate payments disequilibria. Others view flexibility as a major deterrent to world inflation, either because it "bottles up" inflation in individual countries or because depreciations trigger tougher stabilization policies than do losses of reserves—the analogue under fixed exchange rates. Answers to this issue must also encompass the impact, if any, of greater flexibility on levels of world trade and investment and on the demand for international liquidity.

Studies are also needed of the microeconomic effects of more flexible exchange rates. How do they affect foreign direct investment and multinational enterprises; is it a coincidence that Europe feared *Le Défi Americain* only when the dollar became seriously overvalued, and that ratios of foreign direct investment to trade are extremely high for countries whose exchange rates have historically been overvalued (United States, Britain) and low for countries whose exchange rates have been undervalued (Germany, Japan) (Bergsten, Thomas Horst and Theodore Moran)? Conversely, how do multinational enterprises affect the functioning of flexible exchange rates; Raymond Vernon agrees with Richard J. Barnet and Ronald E. Müller that they may render them largely impotent. Another microeconomic question is what exchange rate(s) should be used to test the existence of dumping, or government export subsidies which trigger countervailing duties; this issue is of enormous practical significance since billions of dollars of *U.S.* imports are currently under investigation on one or another of these counts.

A final question on floating rates is whether they have provided more or less stability than fixed rates. Using quarterly spot rates to compare the fixed rate period 1959–1—1973–1 with the floating rate period 1973–2—1975–1, Cline (1976) has found a smaller coefficient of variation during the floating rate period for the dollar rate of the deutschemark, the pound, and the yen, although not for the French franc. Experience is too limited to provide a definitive comparison, but the evidence to date suggesting greater stability under a flexible regime is impressive in view of the special pressures on the international monetary system during this period and in light of the common impression that floating rates have gyrated wildly. Further empirical tests should include examination of the appropriate specifications including periodicity, the measure of fluctuation, and the use of individual cross rates or variously weighted "effective" exchange rates.

### III. Welfare Effects of Trade Liberalization

One key measure of increasing international economic interdependence is the widespread increase in trade-to-*GNP* ratios (P. J. Katzenstein). Yet theoretical, and especially empirical, understanding of international trade flows remains inadequate for answering several central policy questions. These issues have become particularly important in light of two contrary developments: the resurrection of protectionist pressures in a number of countries, and the commencement of the "Tokyo Round" of multilateral trade negotiations (*MTN*) whose aim is the broadest and deepest trade liberalization in history. Do increased trade flows pro-

vide significant welfare gains? Would new trade barriers be very costly?

The traditional measurement of welfare gains from tariff liberalization considers the resulting gain in consumer surplus, net of transfers away from the producers' surplus and government revenue (but adding new government revenue on extra imports if some tariff remains). This measure inevitably yields small magnitudes; it is a fraction of the increase in imports, which itself is a fraction of the base level of trade, which in turn is a fraction of *GNP*. While the removal of very high tariffs generates substantial benefits because the welfare effect rises with the square of the tariff, the tariff structure in industrial countries today is generally low. Indeed, preliminary estimates for a 60 percent cut in all tariffs for the eighteen major industrial countries indicate a global welfare gain of only $1 billion in 1971 dollars, including the welfare gains from substitution among suppliers as the tariff wall declines around countries inside the European Common Market and the European Free Trade Association (Cline, N. Kawanabe, T. O. M. Kronsjö and T. Williams).

The conventional way to derive more impressive results is to appeal to other much more important, usually dynamic, gains. These gains have generally not been quantified, however, and qualitative statements about them are usually unpersuasive to those opposed to liberalization. Thus, for policy as well as scientific reasons, a high priority should be assigned to the development of methodologies for quantifying these gains.

The exploitation of economies of scale should be relatively easy to incorporate, since production function estimates of returns to scale by sector can be combined with predictions of changes in sectoral output levels expected from liberalization. Tests are also needed of the proposition that dynamic gains are derived from increasing efficiency over time in those sectors exposed to freer imports. This could be done by using sources of growth analysis, relating the sectoral residual of technological change to the level of, or change in, protection by sector.

Another approach is indicated by the literature on $X$-efficiency (Harvey Leibenstein). It suggests that, as tariffs fall, inefficiency will be squeezed out of domestic production because entrepreneurs will react to increased pressure from imports by cutting costs. This adjustment might occur even with a competitive domestic market structure; for example, atomistic producers who formerly refused to adopt a technology with high risk but low cost would be forced to do so. The $X$-efficiency approach is subject to measurement (Joel Bergsman), but only under quite arbitrary assumptions. In addition, it cannot convincingly explain why the increases in efficiency do not occur even without liberalization as the result of profit maximization by domestic firms, at least in the competitive case. More generally, the method seems likely to lead to an overstatement of prospective gains from liberalization because in actuality there may be no further room for cost reduction by domestic firms as tariffs fall. Hence it may be less promising than alternative approaches.

A separate but related nontraditional welfare effect is that from increased competition as domestic oligopoly power is reduced by trade liberalization. However, despite the literature on monopolistic competition and the special literature on its response to imports (Richard E. Caves), there exists no specific methodology for quantifying it. There is no method which specifies the correspondence between a percentage reduction of tariffs and the resulting reduction in the degree of concentration (as measured, for

example, by the Herfindahl index), nor any corresponding method for translating these reductions in concentration measures into welfare gains.

Finally, the antinflationary role played by liberalization through all of these effects permits more expansionary domestic policies, and thus creates potential welfare gains through a macro output effect as well as a micro efficiency effect. And analysis is needed of the (largely political) assertion that trade policy itself is unstable, so that the gains from liberalization thus include avoiding the costs of increased trade barriers.

## IV. Trade and Payments Balances

Another area requiring research is the welfare effect of trade balance changes under alternative payments situations. At the policy level, standard trade theory is perceived to have postulated, since Adam Smith and David Ricardo, that any concern about changes in the trade balance is mercantilistic nonsense. Not surprisingly, policy makers reject this absolutist position and pursue their own *ad hoc* assessments of the issue.

Yet the body of trade theory, albeit at a somewhat abstract level, does point to welfare loss from a trade balance deterioration (which can be either exogenous or induced by policy) under a situation of payments deficit. If domestic restraint is employed to offset such a decline, there can be a sacrifice of potential output (James Meade, pp. 171–77). If the exchange rate is depreciated, there will normally be a deterioration in the terms of trade and therefore a welfare loss attributable to a higher real price paid for imports. (This second conclusion, a standard assumption of earlier trade theory, holds even taking account of non-traded goods (Meade, pp. 235–47) so long as supply elasticities of exports and imports remain reasonably high. In more recent formulations the conclusion depends on home and rest-of-world import propensities, in analysis of the transfer problem, but again the "convention" is that a transfer—and therefore depreciation—worsens the terms of trade (Harry G. Johnson, p. 514). Under a situation of payments surplus, on the other hand, a trade balance decrease can mean a welfare gain by providing more goods and dampening domestic inflation.

What is needed is theoretical and particularly empirical work to translate these effects into quantitative measures specifying the welfare change per unit of trade balance change under alternative conditions. In the absence of such guidelines, policy makers facing balance of payments constraints tend to seek trade balance improvements through the use of policy instruments with frequently high costs—export credit subsidization, tax incentives for exports, high preference margins for government procurement from domestic suppliers, efforts to achieve trade balance gains in "reciprocal" trade negotiations, and so forth. The incorporation of explicit measurement of any benefits to be gained from such instruments most probably would have the effect of tempering the excesses of these policies.

Although the move to flexible exchange rates may reduce the urgency of developing such guidelines, they nonetheless remain important. Intervention in the exchange markets persists. And, even with freely floating rates, policy makers should be aware of the welfare effects of specific policy changes via their influence on the exchange rate.

One method of specifying a measure for these welfare effects is to estimate a shadow, or accounting, price for foreign exchange. Given this price, a given change in trade balance will generate a welfare effect equal to the magnitude of the change, multiplied by the ratio of the

shadow rate to the market rate, less unity. For countries in chronic payments deficit, the shadow rate would be above the market rate; for those in surplus, below it. The tradition of purchasing power parity analysis is insufficient for identifying the shadow price, since only by chance will the value of the relaxation of a foreign exchange constraint today be equal to the premium over the market rate implied by a historical tracing of purchasing power parity movements.

For developing countries, there is a substantial literature on estimation of the shadow price (E. Bacha and Lance Taylor). In these countries, where the balance of payments constraint is the most severe, shadow pricing of foreign exchange can reverse some standard conclusions of trade theory. For example, since the formation of a customs union improves the members' joint trade balance by the amount of trade diversion, the normally negative effect of trade diversion can generate positive welfare gains—if the scarcity premium for foreign exchange exceeds the excess cost for purchase of partners' goods rather than outside supply (Cline 1975). (Moreover, since in practice the alternative to integration will be the maintenance of tariffs against partners as well as the rest of the world, this payments improvement will constitute a second-best gain even though elimination of tariffs and their replacement by subsidy incentives might be preferable from an efficiency standpoint.)

### V. Other Issues

The increases in economic interdependence raise a host of other issues for research, many of which have been outlined elsewhere (Bergsten 1973, Peter B. Kenen). One central issue related to welfare gains from trade is the optimal degree of openness of a national economy after taking into account the risks involved in international interdependence. The case for European and Japanese protection and stimulation of their domestic agriculture seems much sounder after their several recent experiences with *U.S.* controls, and threats of controls, on exports of grain and soybeans. The case for a laissez-faire *U.S.* policy toward energy imports appears weak after the actions of the Organization of Petroleum Exporting Countries (*OPEC*). Major savings might be available if there were a body of theoretical analysis on the optimal degree of intervention.

Research is needed on several aspects of the calls for a new international economic order. One issue is the premise that the increase in the oil price benefited the world's underprivileged, which is an important basis for the alliance between *OPEC* and the rest of the developing countries. It seems just as likely that the rise had a highly regressive distributional effect, after accounting for the adverse effects on nonoil less developed countries (*LDCs*) and the poor in industrial countries, and the concentration of oil wealth inside *OPEC* countries. The various schemes of commodity price indexation require analysis to determine the effects on supply and demand, income distribution and worldwide inflation (as indexed *LDC* commodities entered input-output relationships in industrial countries, perhaps with profit margins added at each stage of the transaction). The theory of nonrenewable resource pricing should also be integrated into the analysis of commodity price arrangements.

One proposal in the schemes for a new order, the link between creation of international reserves and foreign aid, would have to be reformulated to focus on the poorest countries in order to be an equitable aid instrument. In any event, the mechanism is unlikely to generate much aid since *SDRs* are unlikely to be created in the next few years (Cline 1976).

The development of theoretical tools for identifying sectors with future comparative advantage is also important in assessing a new economic order, with its tenet of a rising industrial role for *LDCs* in the world division of labor. The importance of the issue is highlighted by the possibility of reductions in the industrial countries' tariff escalation, through the *MTN*. The methodology could also be applied in industrial countries applying selective industrial aids including the United Kingdom.

HARRY G. JOHNSON, University of Chicago: Baldwin's paper is an admirably careful example of professional empirical study of the effects of tariff elimination. The only question it raises is that, whereas theory stresses the "small triangle" welfare gains from tariff reduction, the implied welfare cost in Baldwin's study is the loss of jobs in the affected industries. If this is the relevant measurement, theory needs reshaping. Apart from that, in order to determine whether costs or gains are "large" or "small," we need a standard of comparison. It seems to me that a change requiring an exchange rate change of $\pm\frac{1}{2}$ percent, or the loss of something over a thousand jobs in only a few states over a ten-year period, is scarcely worth worrying about.

Horst's paper is equally professional. My comments are only that in a time of inflation tax deferral involves considerable real savings to the taxpayer allowed to defer; and that I am unhappy with the work on international companies and "domestic monopoly profit." It seems to me that both measured monopoly profit and competitiveness in production abroad are the results of some kind of technological advantage in the broad sense; and that describing the phenomena of the complex economics of technology as a public good produced by private investment in terms of "barriers to entry" is not helpful to understanding.

Bergsten and Cline promise a research agenda; but what they actually offer is a shopping list prepared by a would-be master chef who is so accustomed to eating in first-class French restaurants that he does not know that established firms like General Mills, H. J. Heinz, Pepperidge Farms, and Birdseye exist to make it unnecessary for the home cook to grind his own corn, bake his own bread, and wash his own potatoes. Their list shows remarkable ignorance of both theory and empirical work in the international economic field.

To illustrate, they ask for work on the external corollary of the Phillips curve. Many economists, basing themselves on "rational expectations," doubt whether the Phillips curve exists domestically; work has been done on the same basis for international inflation; and the phenomenon of devaluation-induced domestic inflation is part of the "monetary approach" contention that devaluation does nothing for the balance of payments in the long run. Dynamic gains from tariff reduction have been dealt with extensively in W. M. Corden's *Trade and Welfare;* the same source deals extensively with the allegedly unexplored problem of oligopoly power. Trade liberalization can only be a one-shot palliative of domestic inflation. If policy makers think that the balance of payments can be improved by trade restriction, especially under floating rates, they are repeating a fallacy exploded by Hume two centuries ago and should so be told. The terms-of-trade effect of devaluation, alleged to be ignored by conventional theory, is well known to be capable of going in either direction. A quarter of a century ago Sidney Alexander showed that if a terms-of-trade effect exists, it should be exploited to the optimum restriction point and devaluation used thereafter; earlier, Meade and others pointed to the correct policy of free trade plus international transfers. Finally, it is odd indeed to find *U.S.* government subsidized sales of wheat to Russia, and the actions of *OPEC,* as proof that the free market cannot be trusted. In short, the state of trade theory is quite adequate to the task the authors want to assign it, even though the relevant theory is not known in Washington.

# The Empirical Evidence on the Monetary Approach to the Balance of Payments and Exchange Rates

*By* STEPHEN P. MAGEE*

This paper is a critical review of the empirical evidence on the operation of the international monetary mechanism under both fixed and floating exchange rates. I limit the discussion to recent studies on the monetary approach to balance of payments (*BOP*) and foreign exchange rate (*FX* rate) determination for individual countries.

The "monetary approach" contrasts with the "component accounts" approach to the *BOP* (see, e.g., Martin Prachowny); according to the latter, the *BOP* is determined by combining behavioral equations for all of the components of the *BOP* with the *BOP* accounts identity. The two approaches can be reconciled in a general equilibrium framework with goods, assets and money. But reduced-form estimates of equilibrium in any one of the three markets should include the exogenous determinants of equilibrium in the other two markets. On this score, some of the monetarists err, just as some trade flow and capital flow empiricists, in estimating only a single structural equation rather than a reduced-form equation.

This error notwithstanding, research efficiency dictates that if we want a simple (Occam's razor) explanation of the *BOP* and *FX* rates, then we should examine international money markets directly rather than the international markets for eggs, potatoes and *AAA* bonds. Critics counter that the monetarists actually apply Occam's scimitar to the research victim and that while they succeed in getting down to bare bones, the skeletal remains sustain insufficient life to be worthy of continued scientific interest. This critique misses the point that the monetary approach is a macro theory and that simplicity is an important criterion for any theory which must be understood and used by policy makers.

A second virtue of the monetary approach is that it avoids the error easily made by component analysts of identifying movements in the *BOP* components with identical movements in the *BOP*. For example, increases in home income and prices reduce trade balances and decreases in interest rates cause capital account deterioration. However, all three of these phenomena lead to increases in the demand for money, and hence improvements in the *BOP* (or appreciation of the *FX* rate) according to the monetarists. We turn to the empirical evidence on these monetary pre-

* Associate Professor, Graduate School of Business, University of Chicago. The author is indebted to the National Science Foundation for research support and to Robert Aliber, John Bilson, Paul Evans, Jacob Frenkel, Harry Johnson, Richard Karplus, Arthur Laffer, Aris Protopapadakis and Myles Wallace for useful discussions. They are absolved from any responsibility for the views expressed and for errors.

dictions. Section I examines the *BOP* under fixed rates and Section II examines *FX* rate determination under floating rates, both via the monetary approach.

## I. The Monetary Approach to the Balance of Payments

The *recent* contributors to the monetary approach to the *BOP* include, inter alia, Robert Mundell (1968, 1971), Harry Johnson (1972), Arthur Laffer (1969), Ryutaro Komiya, Rudiger Dornbusch (1971) and Jacob Frenkel (1971). In the simplest empirical formulation of the theory, the demand for nominal money balances is determined by the price level, real income and the interest rate while the supply of money equals the money multiplier times the supply of high powered money (reserves plus domestic credit). When the domestic supply and demand for money are equated and international reserves are separated from high powered money, the monetary equation can be written as

$$(1) \quad r = a_0 + a_1\Delta \log y + a_2\Delta \log P + a_3\Delta \log i + a_4\Delta \log h + a_5\Delta \log d + e$$

$$r \equiv \frac{R}{R+D}\Delta \log R = \frac{\Delta R}{R+D}$$

$$d \equiv \frac{D}{R+D}\Delta \log D = \frac{\Delta D}{R+D}$$

$R$—reserves $e$—error
$D$—domestic credit $i$—interest rate
$y$—real income $h$—money multiplier
$P$—price level

The elasticities $a_1$, $a_2$ and $a_3$ are identical to those in the domestic demand for money equation. In the discussion which follows, I assume that $h$, the money multiplier, is constant. Ordinary least squares (*OLSQ*) can be applied to (1) if there is no sterilization of reserve changes and if the following conditions hold. Real income is assumed exogenous by the long-run full employment assumption; in the long run, prices and interest rates are also exogenous by the small country assumption. This implies that the demand for money is exogenous for the small open economy and that the domestic monetary authorities do not have control over any real or nominal variables in the economy except the domestic component, $D$, of high-powered money and through equation (1), international reserves. If all of the assumptions hold, $a_5 = -1$, so that a \$1 increase in domestic credit leads, *ceteris paribus*, to a \$1 decline in international reserves.

What happens when this long-run theory is subjected to empirical tests applied to short-run data? The results indicate surprising success empirically, even in the simple formulation just outlined. The best single collection of empirical tests on postwar data are the applications of the model to Australia by Richard Zecher, Sweden by Hans Genberg (1975), Japan by Donna Bean and Spain by Manuel Guitian in Frenkel and Johnson. The money demand variables were significant in quarterly equations for three of the countries: Australia, Sweden and Japan. In all three cases, the real income elasticity of demand for nominal money was positive and significant; the price elasticity was significant and statistically equal to 1 and the interest rate elasticity was negative and significant for Australia and Japan. Direct or indirect versions of equation (1) provided good sample period estimates for $r$, the changes in quarterly reserves as a percent of high-powered money.[1]

What conclusions can we draw from this strong affirmation of the monetarist predictions of the effects of $y$, $P$ and $i$ on the *BOP*? *First*, our initial impulse is to be surprised to get such good results from quarterly data based on a long-run model with so many stringent assumptions. How-

[1] $\bar{R}^2 = .89$ for Australia, .76 for Sweden and .65 for Japan.

ever, the overly strong results were obtained partly *because of* rather than *in spite of* these assumptions. The small country, long-run, full employment assumptions allow empiricists to assume that $y$, $P$ and $i$ are exogenous and unaffected by the supply of money. But if they are not, *OLSQ* estimates of (1) lead to simultaneous equation bias. Consider causation the other way. An exogenous increase in reserves which increases the money supply should increase real income, increase prices and reduce interest rates. Thus, without proper specification and estimation, we don't know whether the coefficients in (1) reflect the demand for money or the effects of the supply of money on $y$, $P$ and $i$. All of these money supply phenomena work in the *same* direction as on the demand side and make single equation estimates of (1) overly favorable to the monetary hypothesis.

*Second,* a \$1 increase in $D$ will not lead to a \$1 decrease in $R$ (i.e., $a_5 = -1$) if some money demand variables are excluded from (1). For example, the increase in $D$ will lead to a depreciation of the (excluded) *FX* rate when the latter is within the band set by the exchange authorities. This absorbs some of the excess supply of dollars so that reserves do not fall by \$1. Thus, *OLSQ* estimates of $|a_5|$ which are significantly less than 1 may imply specification error rather than a refutation of the monetary approach. William Branson uses Pentti Kouri and Michael Porter's capital flow estimates as proxies for $a_5$ and cites their results (of $|a_5|<1$) as "not consistent" with the monetary approach.[2] However, these estimates may have been affected by missing variables (which could explain why they found $|a_5|<1$) and their rudimentary treatment of the current account does not, in my judgment, preclude the possibility that a \$1 increase in domestic credit can also lead to a current account deficit (so that Kouri and Porter's capital account proxies for $|a_5|$ are too low).

*Third,* does a \$1 increase in $D$ lead to a \$1 decrease in $R$ if the central bank sterilizes reserve inflows? The answer is "No." If $a_5=-1$, sterilization will lead to *OLSQ* estimates of $|a_5|>1$. If there is an exogenous increase in the home demand for money, caused, for example, by an increase in world and hence domestic prices, then reserves will flow in. If the monetary authorities sterilize partially, reducing domestic credit by some fraction, $s$, of the reserve inflow, then home money demand is still unsatisfied and more reserves will flow in, etc. Thus, *sterilization leads to a magnification effect on reserves*—and thus on *OLSQ* estimates of the coefficients on the right-hand side of (1)—equal to $1/(1-a_5s)$. Genberg (1975) has handled the problem properly, estimating (1) and a sterilization equation simultaneously for Sweden obtaining $a_5=-1.23$ and $s=-.53$. Since he obtained $a_2=1.06$ (the $t$-values for the three coefficients just listed all exceeded 2) the impact effect on $r$ of a 1 percent increase in $P$ is 1.06 percent, while the ultimate effect, magnified by sterilization, is 3.05 percent. Thus, sterilization causes the monetary predictions to work with a vengeance.

The second point above leads us to expect *OLSQ* estimates of $|a_5|<1$ and the third leads us to expect $|a_5|>1$. Because of these offsetting effects, tests for deviations of $a_5$ from $-1$ using *OLSQ* estimates do not constitute a reliable empirical test of the assumptions underlying the monetary approach to the *BOP*. What does the data show? When Genberg accounted for sterilization in Sweden, he did not find that $a_5$ differed from $-1$; *OLSQ* estimates yielded the same result for Australia while

[2] The proxy estimates for $a_5$ are $-.77$ for Germany, $-.58$ for the Netherlands, $-.43$ for Italy and $-.47$ for Australia. All of the estimates are significantly different from $-1$.

$|a_5|$ was significantly less than 1 for Japan. Guitian's estimates for Spain did not differ from $-1$ but his money demand coefficients were insignificant so that his estimate of $a_5$ is probably dominated by the central bank balance sheet identity. Since none of the *OLSQ* estimates exceeded 1 for the four countries, sterilization apparently never dominated the small country long-run misspecification effect while the latter dominated for Japan.

*Finally*, the monetary approach provides a convenient framework for an analysis of discrete changes in exchange rates in a fixed rate system. Mundell and Dornbusch (1973) emphasize that devaluations are purely monetary phenomena, namely a change in the relative price of two currencies. All of the monetarists stress that devaluations affect only nominal variables and not real variables in the long run; some make the same assertion for the short run as well. Since a devaluation raises the domestic price level, it must raise the nominal demand for money. If domestic credit is constant, the increased demand for money can be satisfied only through increased *FX* reserves generated by a surplus in the *BOP:* in equation (1), $r$ increases by $a_2$ times the devaluation-induced increase in the domestic price level. What is the evidence on the significance of $a_2$ when the change in the exchange rate replaces $\Delta \log P$?

Michael Connolly and Dean Taylor used cross-section data to examine 18 postwar devaluations by small developing economies. They found significant effects of the change in the exchange rate on the change in the *BOP* ($\Delta r$) after 2 years.[3] Genberg (1974) successfully tested the monetary approach on 17 postwar devaluations (approximately one-half were developing countries), obtaining excellent fits.[4] Marc Miles combined cross-section and time series data for 14 devaluations and found the effect of the exchange rate on the balance of payments positive and significant for 5 out of the 14 cases. Thus, the evidence is fairly strong that the monetary approach can be used, with relatively minor modification, to explain the behavior of the *BOP* when exchange rates change.

We turn to the avenue by which devaluations improve the balance of payments: Is it through the trade account, the capital account or some combination of the two? The old elasticities models, the absorption model and the early monetary models which have only goods and money (see Dornbusch, 1973) dictated that the improvement must occur through the trade account. More recent models (Dornbusch 1975; Frenkel and Carlos Rodriguez and Johnson 1975) allow for some combination of excess supplies of goods, debt and equities to add up to the excess demand for money induced by the devaluation. Irrespective of the amount of time required for money and asset markets to adjust, Magee (1974) has shown that the trade statistics will be influenced following devaluations by at least as long as the longest contract (order to delivery) period while some trade adjustment processes will last no longer than this period (Magee 1975b). Finally, Laffer (1976) has argued that devaluations will have no effects on trade. His argument runs as follows. If every asset in the economy (including money) has a corresponding liability (for money these liabilities include government debt) and if the net asset position vis-à-vis foreigners equals zero, then a devaluation-induced price rise will reduce real assets and real liabilities by equal amounts. The two can be restored to their original levels by instantaneously exporting capital and importing money, requiring no change in the trade balance; trade is affected neither in the short nor in the long run. The argument is exotic but it deserves exploration

[3] The $t$-statistic on the $\Delta FX$ equals 2.9; $\Delta FX$ plus the domestic credit variable explains two-thirds of the variation in $\Delta r$.

[4] $\bar{R}^2 = .93$ for $\Delta r$ after 2 years.

since the trade data are so erratic.

Laffer's (1976) study of 15 devaluations found little evidence that devaluations improved trade balances. While these empirical results are subject to alternative interpretations (Magee 1975a), they were strengthened in the study by Miles. He found that, after accounting for changes in both $D$ and government consumption, there was a significant positive effect of devaluation on the trade balance in only 3 out of 14 cases, and it was significantly negative in 2 cases. Hossein Askari, Yves Bizien and Ekram Hossain found that exchange rate changes do affect trade but found empirically that the trade balance effects go both ways.

A modification of Laffer's argument could explain these results. The sum of world assets and liabilities are equal by definition. But some countries' net asset positions are *positive* and others are *negative* vis-à-vis the rest of the world. Trade balance surpluses can follow devaluation in the former case and deficits in the latter.

## II. The Monetary Approach to Exchange Rates

Currently, there are two bodies of literature on the determination of exchange rates. One is an outgrowth of the efficient market analysis of securities markets while the other is the monetary approach. The efficient market approach states that $FX$ markets, like securities markets, are efficient in that no single trader can beat the market in an expected value sense. The evidence examined by Ian Giddy and Gunter Dufey and Richard Levich on floating rates in the recent period is not inconsistent with the efficient market hypothesis. John Bilson and Alan Stockman have shown that forward rates are unbiased estimators of future spot rates. The efficient market approach stresses the absence of unexploited profit opportunities and the importance of market arbitrage relationships. (For interest rate parity see Robert Aliber; for the Fisher effect see Eugene Fama; and for purchasing power parity ($PPP$) see Genberg 1975).

The efficient market approach to $FX$ rates is based on rational microeconomic behavior by individual economic agents. The monetary approach to $FX$ rates is a macro theory which attempts to isolate some of the exogenous determinants of equilibria in national money markets and then explains $FX$ rates as the prices which generate simultaneous equilibria among national money markets Exchange rates and other endogenous variables adjust until the existing *stocks* of each currency are willingly held. I relate here the simplest version of the model. Consider money demand in two countries, $i=1, 2$, and assume that the coefficients of $y$, $P$ and $r$ are the same in both countries. Equilibrium in each market implies the existing stock, $M_i$, is willingly held:

$$(2) \qquad M_i = P_i^{c_1} y_i^{c_2} r_i^{c_3} \qquad i = 1, 2$$

$M_i$ = money stock $\quad P_i$ = price level

$y_i$ = real income $\quad r_i$ = interest rate

$c_1, c_2 > 0 \quad c_3 < 0$

If $PPP$ holds, we can write

$$(3) \qquad P_1 = FX \cdot P_2$$

where $FX$ is the foreign exchange rate. Taking logs and letting $c_1 = 1$, we can write the $FX$ rate equation as

$$(4) \qquad \log FX = \log (M_1/M_2) - c_2 \log (y_1/y_2) - c_3 \log (r_1/r_2) + e$$

Equation (4) was successfully estimated for the German hyperinflation by Frenkel (1975),[5] for the $UK$-German exchange rate by Bilson[6] and for four rates vis-à-vis the

[5] Estimates of (4) yielded $\bar{R}^2=.995$ with $c_1=1.0$ and $-1>c_3>0$.

[6] Estimates of (4) from 1968 through 1975 with the $\bar{R}^2=.89$ and significance of all variables except $c_3$.

dollar by Richard Karplus.[7] All three authors estimated monthly equations. The authors found that the coefficient on *log* $M_1/M_2$ were all greater than 1, but the differences from 1 were not statistically significant. Karplus found equivalence of $c_2$ across the 4 countries. This is a virtue since it is necessary for cross-rate consistency.

Several comments are in order. *First*, authors of the recent empirical studies (Bilson, Stockman, Karplus, et al.) are taking great (and in my view, necessary) pains to make their models consistent with market arbitrage relationships and efficient market behavior. These consistency tests are important if we are to avoid macro model *ad hocery*. *Second*, users of these models should not be led into believing that they will beat forward market estimates of future spot rates since these models, if correct will constitute only a subset of the information incorporated in the market price. *Third*, exchange rate changes generate capital gains and losses (expressed in domestic currency) on central bank holdings of *FX* reserves. Central bank behavior may be affected and the mere statistical conversion of reserves into domestic currency units may cause data problems. *Finally*, both monetary approaches (fixed and flexible) identify the stock demands and supplies for each currency exclusively with the domestic holdings of each currency. This assumption is obviously violated by the presence of external currency markets such as the Eurocurrency market.

I conclude the paper with the interesting attempt by Lance Girton and Don Roper to combine the monetary approaches to explain both fixed and floating rate systems. In effect, they separate the international reserves component from $M_1$ in (4) and place reserves for country 1 on the left side of the equation along with the exchange rate. The composite dependent variable is innovative conceptually since it allows disequilibria among national money markets to be resolved by reserve flows, changes in the exchange rate or some combination of the two. Annual estimates for Canada vis-à-vis the United States for the composite dependent variable yielded good fits. Nicholas Sargen extended the approach with success to Japan and the United Kingdom, with less success to Germany and with poor results for Australia. The fits did not deteriorate in the recent floating rate period for Australia, Canada, the United Kingdom, but they did for Germany and Japan (the countries with the largest parity changes). The vice of the approach is that they may be attempting to explain too much with this single equation. The virtues of the approach are that fixed exchange rate regime coefficients of money demand can be carried over to floating rate periods and vice versa; in the absence of structural shifts, three systems (fixed, floating and managed floating) can be explained using a single equation. Occam would be pleased.

[7] The estimation period was 1973 through 1975 with the $R^2$ (and standard errors) as follows: $R^2=.69$ (.034) for Germany; .84 (.031) for France; .74 (.027) for Italy; and .71 (.030) for Norway.

# The Less Developed Countries and the International Monetary Mechanism

By JOHN A. HOLSEN AND JEAN L. WAELBROECK*

The paper discusses the growing involvement of developing countries in the international monetary system.[1] The interest of such a paper would have been slight five years ago. In recent years, developing countries have become large borrowers on the Eurocurrency market; in 1975 they were beneficiaries of over a third of publicized loans. This trend was paralleled by the creation of new International Monetary Fund (*IMF*) facilities adapted to the special needs of these countries' economies.

This paper traces these developments on the basis of a consolidated balance of payments statement for the developing countries which has been synthesized from a variety of sources. The most important are the Direction of Trade statistics, the World Bank's debtor reporting system and the *IMF's* reports on its own operations and on international reserves. Supplemented by Organisation for Economic Co-Operation and Development (*OECD*) information on official grants and private direct investment, estimates of non-trade current account items, and estimates of recent flows from Organization of Petroleum Exporting Countries (*OPEC*) sources, these data of diverse origin add up to a set of accounts which very nearly balances. The residual item—"capital flows *NEI* (including errors and omissions)"—is small, particularly once one accounts for short-term finance in the form of customary lags in payments for imports. (See Table 1.)

The first conclusion is that over the last five years a substantial number of developing countries have climbed into the crowded boat of the international monetary system, which we are trying not to rock. The presence of these new passengers may not make the boat easier to steer; but it is in the interest of all to adjust to their presence. This is recognized in representation the developing countries have in the Interim Committee —the ministerial level group considering reforms in the international monetary organization. It is also reflected in the attention being given to compensatory financing arrangements and the United Nations Conference on Trade and Development (*UNCTAD*) proposals for an integrated commodity program. These discussions are not just about how aid can be channelled to the poorer countries, or even just about the "New International Eco-

* Members of the staff of the International Bank for Reconstruction and Development (*IBRD*); J. Waelbroeck is on leave from the Université Libre de Bruxelles. They are grateful to Wouter Tims, Jo W. Saxe and Elinor Y. Sachse for perceptive comments. The views are their own and should not be quoted as representing those of the World Bank Group, which takes no responsibility for them. The paper deals with very recent developments on which there is as yet very imperfect information. The authors alone bear responsibility for errors of fact or interpretation.

[1] For shortness' sake we will use the term "developing countries" to refer to the subgroup of such countries which excludes the important petroleum exporters as well as countries in Southern Europe and among the centrally planned economies which may sometimes be included under this heading. More specifically, the countries included are those currently classified in the *IMF/IBRD* Direction of Trade statistics as "less developed countries" excluding the group of 17 "oil exporting countries." We will refer to "lower" and "middle income" countries as separate groups. The dividing line is drawn at a level of $200 per capita *GNP* in 1973.

nomic Order" sought by the developing nations; they also correspond to the enlightened self-interest of an international financial community which can only benefit from creating a safety net which reduces the risk of default of large clients.

To be fashionable, the next conclusion is about the new international economic order. Recent developments have demonstrated that through their involvement in the international economic system developing countries have gained a substantial freedom to allow their economies to diverge from world trends. If, as Etienne Kirschen has suggested, economic sovereignty should be defined in terms of power to control a full range of policy instruments, then, by gaining access to borrowing on the international monetary market, middle income developing countries have made a significant step towards the new type of international relations which the third world is demanding today.

It is hardly necessary to stress that these developments also entail risks. They require new debt management skills on the part of the borrowers, as well as willingness on their part to carry out painful adjustments rather than to allow debt to pile upward. An effort is required also of developed countries, from banks which have to weigh the distribution of their risks, and from governments and international institutions, which will inevitably be called upon for help on occasions.

Finally—and this is a conclusion which is never repeated enough—these developments have increased even more the gap between middle and lower income countries. Over the past five years, middle

income countries have achieved per capita rates of growth of 4 percent, while gaining a new freedom to control their economic destiny. During the same years, there has been no growth of income per capita in the lower income countries; especially since the rise in oil prices, these countries have become increasingly dependent on concessionary aid.

### I. Balance of Payments Developments in 1970–75

Table 1 summarizes balance of payments developments in developing countries in 1970–75. By 1975, as the boom was drawing to a close, the middle income developing countries were in a particularly strong balance of payments position. Inflation had reduced the real cost of servicing their foreign debts. A number of developing countries had experimented with more outward oriented trade policies, which had proved very successful in expanding the level of their exports. Many of those countries found that they owned record foreign exchange reserves, which were increasing steadily.

The situation of the lower income developing countries was much less favorable. The most important of these countries are those of the Indian subcontinent, where agriculture had suffered from a series of unfavorable monsoons. Their exports remained very small in comparison to their *GNP* and had expanded rather slowly. As a result the ratio of their foreign debt to export earnings was about twice as high as that of the middle income developing countries. Since a large share of aid to these countries consists of concessionary loans, the debt service to exports ratio was only a third higher than for other developing countries.

Around 1970, developing countries began using the Eurocurrency market as a source of investment credits as well as trade finance. Lending from banks to the developing countries expanded rapidly, growing (on a net disbursements basis) from $200 million in 1970 to $3.7 billion in 1973; by the latter year it accounted for 40 percent of the net disbursements from medium and long-term public loans.

These operations brought developing countries into a new type of relation with the world's financial and banking system. Previously, most of the private capital entering developing countries moved at the initiative of investors in developed countries. Except for trade credits, these capital flows, like aid flows, disbursed quite slowly. Developing countries always had a choice between policies of encouraging or discouraging private capital imports, but these policies operated slowly. Bank loans, because they can be negotiated swiftly and drawn down immediately, and can therefore be used to offset sudden pressures on the balance of payments, fill a gap in the arsenal of policy tools.

Only the middle income countries had access to commercial bank lending. To commercial banks the lower income countries did not appear as particularly attractive risks; the poor countries on their part recognized that they could not afford to bear the cost of borrowing on commercial terms. The export earnings of the poorer countries self-financed—more out of necessity than choice—85 percent of their imports in 1970–73; by comparison, the exports of the middle income countries financed only 80 percent of their imports.

Both groups of developing countries were dealt brutal blows by the rise in oil prices and by the onset of the world recession. The rise in oil prices directly added some $10 billion to import costs in 1974. In absolute terms, middle income countries bore the largest share of the cost. But the burden which the poorer countries had to bear represented a larger

share of their exports. The impact of the recession, by contrast, was most strongly felt by the middle income countries, many of which export minerals and manufactures whose export demand is quite elastic.

The ability of developing countries first to stave off, and later to mitigate the impact of these balance of payments pressures on their economies has surprised observers. One factor which helped finance a high level of imports in 1974 was the large increase in credit that automatically accompanies an expansion of imports; an average payments lag of only one month amounts to more than $4 billion in additional short-term commercial credit when imports grow as rapidly as they did between 1973 and 1974. *OPEC* lending was an important new source of finance which became available during this period. This went both to middle income and to low income countries.

Inflation in 1974 and 1975 has been indirectly helpful. Developing countries are large net borrowers: their foreign debt, net of foreign exchange reserves, was $38 billion at the end of 1973. Every percent of world prices inflation wipes out $380 million of this debt. We assume here that inflation affects only the level of prices, and not the terms of trade of primary products versus manufactures.

It is however the new access to commercial bank borrowing which has made substantial balance of payments deficits possible for the middle and higher income countries. The range of countries which found themselves sufficiently creditworthy to obtain loans from commercial banks is remarkably wide. In 1974 and in the first nine months of 1975, 28 developing countries were involved in the publicized Eurocurrency credits identified in the *IBRD* International Finance Division's quarterly review of the Eurocurrency lending; of these, half may be considered as regular borrowers.

These new members of the international monetary system are accepting substantial risks to maintain the momentum of their growth. Their exports are very sensitive to business fluctuations and their import needs tend to be rigid. They have substantial, fairly short-term foreign debts. Their access to lending of last resort, at the early December 1975 date of writing of the paper, is not proportioned to those risks, though several measures discussed in current negotiations could improve it. The proposed *UNCTAD* integrated commodity program is an example of what is needed. In the *IMF* context, the clauses of the compensatory financing scheme should be modified to enable that scheme to function effectively in a world of inflation. This could provide developing countries with a safety net similar in nature to, but more adequate in size than the *EEC* Stabex scheme agreed on earlier in the year. Developing countries would benefit from any general increase in *IMF* credit tranches. The proposed *IMF* Trust Fund, though it is not designed for short run balance of payments stabilization, would provide *LDC*s with foreign exchange at a critical juncture. Such arrangements would be in the interests of the whole of the international financial community.[2]

The lower income countries, whose *IMF* quotas are very small, have little access to the Fund's regular balance of payments relief lending. An adequate compensatory finance scheme would be helpful to them. The most helpful facility for those countries has been the *IMF* Oil

[2] Added in proof: The access of developing countries to lending of last resort has been improved substantially by the December 24, 1975 reform of the *IMF* Compensatory Finance Scheme, as well as by decisions taken in the January 1976 Jamaica Meeting of the Fund, which increased all credit tranches by 45 percent and organized the Trust Fund. The December 1975 negotiations on the *UNCTAD* integrated commodity programs were unsuccessful, and it does not seem that these negotiations will reach results speedily.

|---|---|---|
| Estimated balance of payments borrowing (billions current dollars) | 7.8 | 11.3 |
| Amount of drop in *GNP* required to close balance of payments in absence of such borrowing | −5.0% | −6.9% |
| Impact on aggregate demand in developed countries | .4% | .6% |

Facility. In 1974 and in the first ten months of 1975, $2.1 billion were loaned to the developing countries under this arrangement. Over half—$1.2 billion—of this went to low income countries.

## II. Deficits and Their Consequences

If external funds had not been obtained rapidly, developing countries would have been caught short by the recession and by the increase in oil prices, and forced to restrict imports drastically. Since in many of these countries nonessential imports are already excluded by strict controls, this would have led to severe disruption of investment and economic activity.

It is not usual in analyzing business cycle developments to think of developing countries as capable of affecting aggregate demand. This is because they are thought of as adjusting their purchases passively to the level permitted by their foreign exchange earnings. This assumption is not correct any more. Less developed countries (*LDC*s) import policies influence demand today in the same way as the *U.S.* deficit of the late 1960's and early 1970's, and the *OPEC* balance of payments surplus. It is worthwhile to evaluate this influence.

The extent to which developing countries would have had to cut back economic activity if they had not had prompt access to additional funds can be estimated using the *IBRD*'s Simlink model. (See Norman L. Hicks.) This model describes the mechanism through which developing countries adjust their imports to the available amount of foreign exchange by changing the level of their *GNP*. We have assumed that in the absence of extraordinary balance of payments financing, foreign exchange reserves of middle and higher income countries would have dropped by $2.0 and $5.0 billion in 1974 and 1975, and that the "normal" capital inflow would have increased from the 1973 level of $17.1 billion with inflation. (See Table 2).

The impact of the *LDC* import surplus on developed countries can be measured using the *IBRD* Multilink system of dynamic multipliers, built up on the basis of simulations of the Link system and of the Desmos *EEC* model. (See Andre Dramais, Waelbroeck and Bert Hickman.) These simulations, which measure the impact on *GNP*s of a change in demand in developed countries, have been used to construct a matrix of demand impacts which is a convenient tool in business cycle analysis. Allocating the *LDC* imports in proportion to developed countries' exports, we see (Table 2) that developing countries have had a perceptible impact on business trends in developed countries. Their balance of payments deficit has sustained demand as much as, say, a vigorous German demand expansion.

The impact on the Eurocurrency market has been particularly important. In 1975, between a third and two-fifths of publicized Eurocurrency credits went to developing countries. The evolution of this key market would obviously have been different if developing countries had not

appeared as creditworthy borrowers. Of course, lifting the veil of institutions, we see that the middle income developing countries have used the Eurocurrency market to borrow a share of the *OPEC* surpluses to finance their oil deficit.

### III. Implications for Reform

In 1975 a number of developing countries have been taking steps to restore balance of payments equilibrium. The *GNP* growth of the middle income countries has slowed down.[3] It nevertheless appears that these countries will have to continue to borrow heavily next year.

That this seems possible is partly due to the exceptionally strong balance of payments and creditworthiness situation of the middle income countries at the turn of the business cycle. The sharp world inflation in 1974 and 1975 has moderated the fall of commodity prices, holding debt service to exports ratios at acceptable levels given historical experience. Exports of manufactures from middle income countries proved surprisingly resilient to the recession.

The fact remains that the middle income group has chosen a course of action which involves risk. The risk is not borne by each country in isolation: any spectacular setback would affect the creditworthiness and growth prospects of the other middle income countries, and would weaken the financial system of developed countries at a very inopportune time.

[3] Thanks to the good monsoon in the Indian subcontinent, growth of the lower income countries has accelerated sharply.

The shock which the latter system would have to absorb would not be very large, however: it could be roughly compared to the impact of serious default by New York City, compounded by the resulting difficulties which would result for other U.S. cities. For the middle income developing countries, the shock would be far greater. These countries' *GNP* is some 7 percent above the level which could be sustained in the absence of balance of payments borrowing, and they would have to resort to very drastic cutbacks in their development programs.

The extent of the risk depends on the pace of recovery, and on the extent to which inflation will continue to whittle down the value of debts as they accumulate. It is clearly desirable to reduce this risk by providing developing countries with a safety net adapted to the special characteristics of their economies. This could be provided in the framework of *IMF*, but other solutions are possible, such as an expanded export stabilization scheme, or the proposed integrated commodity scheme.

# How to Fill an Empty Shell

*By* JÜRG NIEHANS*

Two years ago the International Monetary Fund (*IMF*) moved into its new building. It is essentially a shell of offices, 13 stories high, enclosing a glass-domed atrium. The symbolism is hard to resist: In that same year the gold/exchange standard for whose protection the *IMF* had been set up, finally collapsed, leaving the institution as an administrative shell devoid of guiding principles. The basic problem of the international mechanism is how to fill this empty shell.

## I. The Challenge: The Collapse of Commodity Money

The problem arose because of the collapse of commodity money. The gold/exchange standard of Bretton Woods, while providing considerable autonomy for national stabilization policies in the short run, required long-run national price trends in line with production costs in the gold mining industry and thus precluded secular inflation. This constraint was not regarded as a sacrifice imposed on member nations for the sake of international cooperation, but as an expression of the old insight that secular inflation has only costs and no benefits. In particular, the gold constraint was perfectly compatible with the objectives of *U.S.* economic policy as expressed in the Employment Act of 1946 and its subsequent interpretations. As long as these objectives were adhered to, the system could, in principle, last forever. It collapsed essentially because of an abrupt, but lasting change in the course of *U.S.* monetary policy. To identify such a change in a fixed-rate system, the monetary theorist will not examine $M^1$ or the monetary base, since both are determined by the joint monetary policies of all countries and reflect *U.S.* monetary policy with a lag. What he will examine is rather the volume of Federal Reserve credit; this is what *U.S.* policy really controlled. The result, summarized in Figure 1, is remarkable. Up to 1960 the rate of Federal Reserve credit expansion per congressional term was in reasonable conformity with the objective of long-term price stability, generously interpreted; both World War II and the Korean War were followed by contractions, and in the second half of the 1950's the expansion rates were moderate and fairly constant. In 1961, however, the rate of credit expansion increased about sevenfold almost overnight. The shift was not only large and abrupt, but also lasting in nature, and the inflationary course set in 1961 remained unchanged for the next 14 years under three administrations.[1]

What was the reason behind the shift in *U.S.* policy? I believe the main reason was a deficiency of the mainstream economics of 15 years ago. Most of the highly regarded economic theorists shared the notion, based on the Phillips curve, that a lasting reduction in unemployment could be bought at the price of moderate and nonaccelerating inflation. Today we realize, if we did not realize it then, that this

* Abram G. Hutzler Professor in Political Economy, The Johns Hopkins University.

[1] Figure 1 also shows that the annual compound rate of growth of Federal Reserve credit over twelve-year periods was more than five times as high for 1960–72 as it was for 1948–60. It is interesting to note that $M^1$ lags behind Federal Reserve credit during the 1960's and that the lag disappeared when the fixed-rate system collapsed, just as monetary theory for an open economy would make us expect.

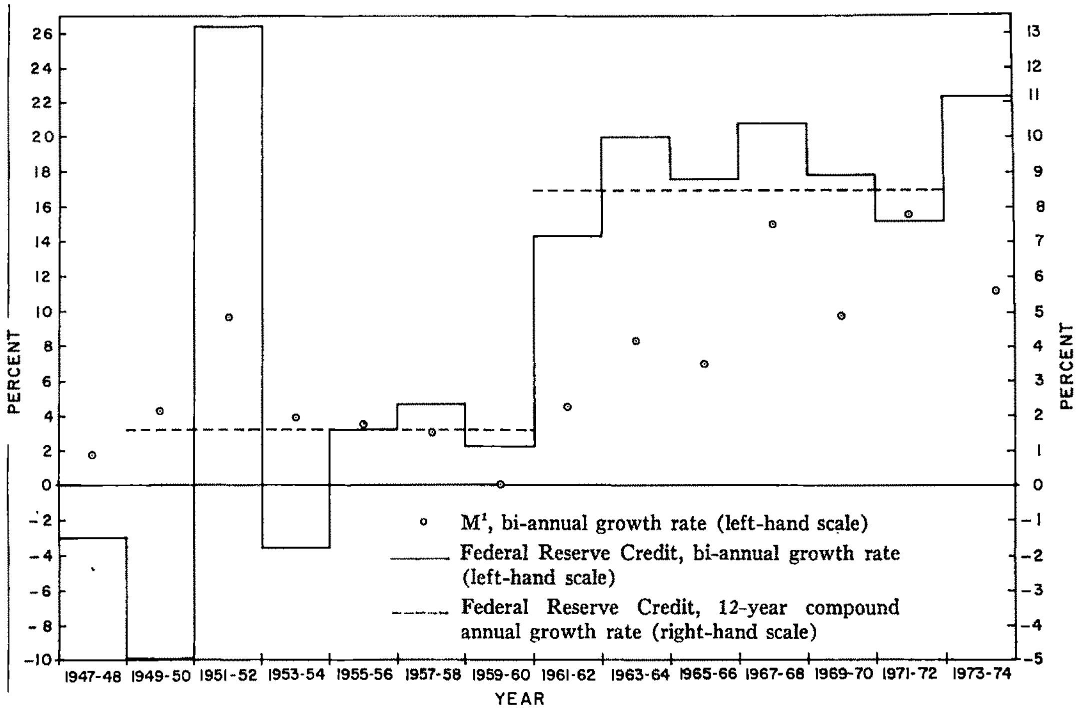

FIGURE 1

notion is, in fact, an illusion. It was under the spell of this "Phillips curve illusion" that the United States changed its monetary course to secular inflation.

Through the fixed-rate system the *U.S.*-generated inflation spread to other nations. If the other countries had consistently used the normal defense of converting dollars into gold, we might still have a viable international system, though probably with a devalued dollar. As it was, most countries, just having recovered from the dollar shortage, eager to show themselves cooperative and suffering from the same Phillips curve illusion, made little use of this defense. As a consequence, the American monetary expansion led to the collapse of the system. This collapse was not the result of technical deficiencies or internal contradictions in the system. It was the result of specific errors in economic judgment at a particular turn of history. Correspondingly, the successful development of new monetary mechanisms will not be a matter of inventing schemes and techniques but of the basic orientation of *U.S.* monetary policy.

## II. Short-Run Response: Adaptation to Inflation

The short-run problem for the international monetary system is to adapt to the inflationary environment created by the Phillips curve illusion. This means, in the first place, that exchange rates between core countries must continue to float and that the efforts to reconstruct a system of "stable but adjustable" rates should not be revived at the present time. These efforts were doomed to failure because central banks which find it impossible to resist the Phillips curve illusion will also find it impossible to submit to an international "harmonization" of monetary

policies. I also believe that in the absence of constraints on the money supply a fixed-rate system is more inflationary than a floating rate system, because it permits each country to externalize a part of the inflationary cost of its own policies which, by a familiar argument, leads to an overproduction of inflation. The immediate reform efforts should thus be concentrated on making floating rates work. To the extent that this is the *U.S.* position, I believe this position is right.

This has a number of implications. First, the process of the demonetization of gold should be completed by allowing central banks to buy and sell gold at competitive market price. It has been argued that a revaluation of central bank gold would be inflationary. I believe this argument is fallacious, because the behavior of central banks depends on what they perceive the true market value to be and not on the artificial numbers used by their bookkeepers. The *U.S.* vendetta against free-market gold serves no constructive purpose and should be abandoned. The monetary role of gold, large or small, will then be decided by market forces.

Second, reformers should stop worrying about the so-called dollar "overhang"; it has been taken care of, not by the oil crisis, but simply by the floating of rates. This can be generalized. There have been many expressions of concern about the lack of control over international liquidity, and ingenious remedies have been proposed. Under floating rates both the concern and the remedies are unnecessary. It is indeed true that there is no longer an international reserve constraint, central banks accumulating foreign exchange reserves at their discretion. It is also true, however, that international reserves have lost their significance for inflation or deflation in the world economy, each country now controlling its own price trend. It can be left to each central bank to determine the proportion of reserves in its total assets.

The third point relates to Special Drawing Rights (*SDR*). With the value of the *SDR* now pegged to a composite bundle of 16 currencies, their interest rate determined by formula and their quantity fixed by administrative fiat, there is no market variable left to adjust to changes in demand and supply of *SDR* relative to the component currencies. This threatens to create a typical Gresham problem of alternating "overhangs" and "shortages": either everybody wants to obtain *SDR,* but nobody is willing to give them up, or everybody wants to pay in *SDR,* but nobody is happy to receive them. To some extent this problem can be suppressed by *IMF* directives, but if it is not solved it will probably prevent the *SDR* from ever becoming a major element of the international monetary system. To solve it, the *IMF* could either decide to buy and sell *SDR* freely against the composite currencies, thus letting the quantity of *SDR* be determined by the market, or permit the value of *SDR* to fluctuate against the composite unit of national currencies. Actually, the 1974 model of *SDR* is devoid of economic significance for the system as a whole, for it is simply a composite of 16 currencies, and reserves in terms of the composite unit can be "homemade" by the 16 central banks exchanging their currencies among themselves. As a consequence, the *SDR* has, in effect, been reduced to an instrument for international transfer payments, and even in this capacity it could just as well be replaced by national currencies.

Under the circumstances, the one important short-run function of the *IMF* seems to be the development, promulgation and enforcement of guidelines for foreign

exchange policies under floating rates. A first set of such rules was, in fact, issued last year. The question is how they might be made more specific. I shall now make six highly tentative and exploratory suggestions on this point.

The first three propositions are of a negative nature. First, I believe there should be no quantitative rules with respect to reserves or foreign exchange transactions at the present time. Trade flows react to exchange rates with a "long and variable" lag (for recent evidence see Helen B. Junz and Rudolf R. Rhomberg), and if, in the case of monetary changes, the eventual working of the purchasing power parity principle gets to be correctly anticipated, they may hardly react at all. In a sense this is desirable because it helps to insulate output and employment against exchange rate fluctuations. At the same time, however, it tends to produce a persistent "overshooting" of these fluctuations accompanied by a large increase in exchange risks (see Rudiger Dornbusch). Central bank intervention to reduce this overshooting, *if based on superior foresight,* might thus, in principle, be beneficial. At the present time, however, reliable criteria for such intervention cannot be established. As a consequence, the *IMF,* while continuing its research on the subject, should refrain from formulating quantitative guidelines, leaving it to the central banks to develop their own criteria and to experiment, individually or jointly, with different intervention systems, perhaps including the crawling peg, dual rates, reference rates or purchasing power formulae.

Second, there should be no quantitative restrictions on the Eurocurrency operations of central banks. The recent performance of the Euromarket has confounded those experts who predicted an imminent crisis, confirming earlier doubts whether they had really a correct understanding of this market. My best judgment is that the Euromarket is a relatively stable segment of the total credit structure, that its liquidity-creating potential, if any, is very low, and that shifts of funds between *U.S.* securities and Eurodeposits, comparable to shifts between different segments of the *U.S.* market, are of minor importance for the international monetary system (see Niehans and John R. Hewson).

Third, there should be no quantitative restrictions on short-term capital flows. Even under the Bretton Woods system speculative capital flows, so often used as a scapegoat for the failures of monetary policy, were not the source of the trouble, but only a symptom of it. Under present conditions they are, in fact, one of the principal stabilizers of exchange rates.

Propositions four to six are positive, but qualitative rather than quantitative. The fourth rule says that central banks, if they wish to create or destroy domestic money by buying or selling foreign assets, should continue to use interest-bearing foreign securities or time deposits rather than foreign cash balances. Since the basic purpose of floating rates is to give each central bank a high degree of monetary autonomy, the influence of country *A* on the money supply of country *B,* while it cannot be completely eliminated, should be reduced to a minimum. This can be achieved by using foreign cash balances only for transactions purposes and using less liquid foreign assets for the accumulation or decumulation of reserves.[2]

My fifth rule is in the same spirit. It says that foreign reserves should be denominated in dollars or in a broad-based composite currency like *SDR.* In both cases the remaining effect of national

[2] This rule would automatically take care of the real problem with the Eurodollar market, which resulted from the large-scale shifts of reserve funds from liquid dollars into less liquid time deposits; if the central banks had shifted into treasury bills, the problem would have been essentially the same.

monetary policy on the rest of the world is spread over a large money market. On the other hand, if "small" currencies like the mark, sterling, or, in the extreme, the Swiss franc are used, there could be a concentrated effect on the German, British or Swiss money market. The United States, in particular, should not undertake large operations in any individual foreign currency, since this might reduce the monetary autonomy of the respective country almost to zero.

The sixth rule, finally, has to do with the relative use of domestic and foreign assets in the conduct of monetary policy. The central bank is confronted with two stabilization problems, the more important one relating to short-run fluctuations in domestic output, the less important one relating to short-run fluctuations in exchange rates. To do its job, the central bank has two instruments, namely operations in domestic assets and operations in foreign assets. In most cases, both instruments will affect domestic demand in the same direction, and the same will be true for exchange rates.[3] The question is how much. It is plausible to conjecture that \$100 million of domestic asset purchases have a relatively stronger effect on domestic demand, while \$100 million of foreign asset purchases have a relatively stronger effect on the exchange rate. If this conjecture were shown to be correct, Robert Mundell's assignment principle could be used to derive the sixth rule. It says that open market operations should be used for domestic stabilization, while foreign exchange operations should be used to stabilize the exchange rate. At the present time, this rule is subject to the qualification that the validity of the underlying conjecture has not been analytically established. The examination of this problem seems to be one of the more urgent small research problems in this field.

I believe that workable guidelines for managed floating can be developed along these lines. To be sure, the result of such a passive adaptation to secular inflation will be no better than second-best. In particular, the hoped for gains in the effectiveness of monetary policy will probably not materialize (see Niehans) and the increased exchange risk will gradually lower the international specialization in production and increase the international diversification of portfolios. However, as long as national money supplies, determined by myopic governments under the spell of the Phillips curve illusion, are not subject to a long-run constraint, this seems to be all the *IMF* can do for the international mechanism.

### III. Long-Run Response: Monetary Constraints

In the long run we should be able to do better. However, real progress cannot be expected from international initiatives, but only from the willingness and ability of governments to constrain the national money supplies over periods of 3–5 years to roughly the rate of real growth. Under one variant, each of several countries, while retaining the flexibility for short-run stabilization, would maintain such a noninflationary trend. Their exchange rates would still fluctuate, but probably not much; speculation would tend to be strongly stabilizing. This could be quite a satisfactory system. Alternatively, the national money constraints could be replaced by an international constraint combined with fixed exchange rates, perhaps with a rather wide band. The *IMF* could then again play its traditional role of strengthening the fixed-parity system

[3] There is some slight ambiguity with respect to purchases (or sales) of foreign securities, since they produce a decline (increase) in foreign interest rates which could result in a capital inflow accompanied by a trade deficit. The latter might conceivably nullify the stimulating effect of the domestic monetary expansion.

by increasing its flexibility through lending. In this case, the national money supplies would deviate from their ideal paths, but again not very much. This is the situation in which the choice between fixed and floating rates, the optimal currency area problem, would finally become a real issue.

The international constraint, if any, could be constructed in different ways. Under an *SDR* standard the amount of *SDR* could be increased by, say, 4 percent a year simply by the payment of interest on outstanding balances; no studies on the "need" for reserves would be necessary. National currencies would then be pegged to *SDR*. While such a system would have some attractive features, it seems unlikely that it can be realized within, say, a decade. Before the *SDR* could serve as the international monetary base, it would have to develop into the principal reserve asset whose total amount has reached a steady state. It is hard to imagine how the *SDR*, created by administrative fiat with little appreciation of market forces, could be brought to this mature state in the foreseeable future.

A second alternative is the return to an international gold standard. While this has the familiar drawbacks, it is the only system of which we know from historical experience that in a noninflationary world it is workable. However, an official return to gold parities by international agreement does not seem likely, because in the absence of secular inflation it offers no significant advantages and in the presence of inflation it is not feasible. I tend to believe, therefore, that a reconstruction of the gold standard, if it should ever take place, would rather begin in the private sector under the pressure of market forces. A distinctive feature of commodity money is its ability to be created and supplied by competitive firms. Indeed, the postwar gold/exchange standard was not an ingenious scheme invented by experts at Bretton Woods, but simply the codification of a system that had evolved spontaneously over centuries. If official monetary policies should further deteriorate rather than improve, gold may play an increasingly important role as a financial asset, as a medium of exchange and a medium of account. After years of secular inflation, governments may then be voted into power which are willing and able to ratify this development by tying their decaying currencies once again to gold. Monetary history would have come full circle. Such perspectives, while vague, should remind the central banks to keep their gold options open. The surest way to prevent the return to gold is to adopt a monetary policy that is not widely different from that under a gold standard.

The third alternative is the dollar standard with the *U.S.* money supply subject to a long-run constraint and other countries pegging their currencies to the dollar. This system would clearly be asymmetrical in the sense that short-run stabilization would be somewhat easier for the *U.S.* than for the other countries. I believe, however, that this drawback would be tolerable and more than balanced by the advantage that this arrangement, with a stable *U.S.* monetary policy, would be eminently workable. In fact, *provided* the core countries bring their money supplies under control, this system is most likely to emerge spontaneously under the pressure of market forces. Probably it is also the system into which the Bretton Woods system would gradually have evolved had the U.S. not changed its monetary course in 1961. In the late 1960's the dollar standard was an American dream, the dream of a bankrupt wildcat banker. For a solid world banker the dream may easily become true. I believe, therefore, that recent *U.S.* efforts to make the international monetary system more symmetrical were shortsighted; like "benign neglect" they were a symptom of

failing leadership. To accept leadership by putting *U.S.* monetary policy back on a noninflationary course, thus encouraging the emergence of a dollar standard, seems to be the most realistic and most promising approach to international monetary reform. The basic problems of the international monetary mechanism are really a problem of *U.S.* monetary policy.

HOSSEIN ASKARI, University of Texas: I would like to direct my comments to the paper by Jürg Niehans and in so doing I will have also indirectly addressed the issues presented in the other papers. Niehans is concerned with three related issues—first, the collapse of the Bretton Woods (*BW*) System; second, the short-run management of the current payments system; and third, the long-run reform of the international payments system. Let me take each of these in turn.

Niehans maintains that the *BW* System collapsed because of the lasting expansionary course of American monetary policy which began in 1961. I find this argument either one-sided in its historical perspective or restrictive in its interpretation of *BW*. In the first place, the United States was, for a long time, blamed for the so-called dollar shortage. Then in the 1960's, it was accused of creating a dollar glut. So initially the complaint was one of too strong an American balance of payments position and later it turned to one of too large a deficit. It is clear that if the Europeans were not accumulating enough dollars, they could have devalued with respect to gold and if they were getting too many dollars, they could have revalued. I would, however, agree that the same result could have been achieved if the United States had changed the parity of the dollar to gold; but it chose not to, I think, for good reasons. But, in any case, the rest of the world had a very powerful and direct mechanism for correcting any complaint. Niehans could, however, argue that continuous changes in parity was against the "spirit" of *BW*. I would find such a position as subjective.

In regard to the desired management of the current system, I have two related concerns. First, I think that there should be available a constant purchasing power (in terms of internationally traded goods) and interest bearing Special Drawing Rights (*SDR*). My reason for this is that the oil exporting nations are currently wasting a great deal of resources in haphazard development plans largely because they feel that they have to spend their oil receipts immediately. If, on the other hand, such an *SDR* was available to them, they would be more willing to acquire such an asset in lieu of wasteful development and be possibly motivated to expand output and reduce oil prices. Second, the major balance of payments deficit now resides with nonoil exporting developing nations. But no exchange system can alleviate their deficit position. However, the International Monetary Fund (*IMF*) could, by acquiring *OPEC* balances through the creation of this new *SDR*, make large loans to finance development of such nations. Thus a larger Organization of Petroleum Exporting Countries (*OPEC*) surplus could be indirectly used to finance development of the largest segment of the world population.

In the long run, I agree with Niehans that we should be able to do much better. Any viable long-run system must incorporate some flexibility in allowing for relative autonomy in domestic policy and further not be disruptive in causing unnecessary short-run shifts in resources which are not dictated by long-run scarcities.

Any system of fixed exchange rates will be limiting, as Niehans has pointed out, in flexibility of differing domestic goals. No nation is, I believe, willing to again abdicate control of its domestic monetary tools as required under a system where exchange rates do not change, or at least, do not change frequently.

A system of floating rates, though desirable on many grounds, has two major drawbacks. First, large fluctuations in rates can cause transfers of real resources which may not be desirable from the long-run perspective. Second, and probably much more controversial, floating rates may enhance world wide inflation. I have come to this tentative conclusion from some casual empirical and theoretical considerations.

Economists have, since the writings of Keynes, agreed with the proposition that prices, although flexible upwards, tend to be sticky downward. Furthermore, since the theory of Absorption, the notion that devaluation will, in time, lead to pressures on domestic output, thus increasing prices and leading to an eventual deterioration of the

trade balance is commonly accepted. Therefore, by combining these two pieces of received theory, we can provide a mechanism for world inflation.

A devaluation increases domestic prices. But given that prices are sticky downwards, a revaluation may, on the other hand, only moderate price increases but does *not* lead to price decreases. Clearly if price declines would have occurred in the absence of downward stickiness, then this basic asymmetry becomes crucial. More simply, if a country's exchange rate depreciates by 10 percent, then this will add to inflation by $a$ percentage points; if, at a later date, the exchange appreciates to its old level, then inflationary pressures will be reduced by $b$ percentage points; now because of the basic downward stickiness of prices, $a$ is greater than $b$ and thus the overall impact on inflation is a positive one. In essence, over the time period the exchange rate has not changed (it first depreciated but then it appreciated to its initial value) but because of exchange fluctuations, inflation has increased.

Beginning in August of 1971, many currencies have, with varying degrees of official intervention, floated on world exchange markets. At times, these fluctuations in exchange rates have been *very large*. Thus, these exchange fluctuations, through the mechanism described above, could have contributed substantially to the recent surge in world wide inflation which became substantial beginning in 1971. A casual glance at the data suggests that this ratchet effect of exchange fluctuations could have been the major contributor to world-wide inflation. However, a full scale econometric analysis is needed to assess the significance of this process.

Based on the above casual reasoning and more importantly on ideas expressed in two joint papers with Franco Modigliani, I would recommend a system of sliding parities to provide the best long-run system of international payments.

INDEXATION—MONETARY CORRECTION?

# Government Intermediation in the Indexed Bonds Market

*By* DAVID LEVHARI AND NISSAN LIVIATAN*

Various arguments have been presented in favor of government issuing linked bonds. A well-known argument is that in inflationary periods the government should enable the "small investor" to maintain the real value of his savings. Another argument, which has been made recently, is that the stock of government indexed bonds issued will reduce the government's incentive to use "inflation" as a tax. We do not wish, however, to discuss these arguments, or similar ones, which are based, essentially, on some political or social conceptions. (One could argue as an example that indexing of the government debt makes the inflationary tax a less effective tool and the government may be forced to inflate even more in order to acquire a given amount of real resources from the public.) Instead, we shall concentrate on a class of arguments which stress one major aspect of the problem: that by issuing indexed bonds the government reduces the *inflation risk* faced by the economic agents.

It has been argued that the introduction of a risk-free asset enlarges the feasible set of the private investor and enables him to achieve a better diversification of his portfolio. In addition to this direct contribution to the welfare it is argued that the existence of linked bonds encourages savings under inflationary conditions and reduces the tendency to make excessive investments in real estate and other physical assets. This, it is argued, will reduce the pressure on real resources of the economy and hence reduce the inflationary pressure. Advocates of linked bonds consider these properties to be desirable under inflationary conditions.

In the present paper we take a critical view of these arguments for and against indexed bonds. We shall first argue that it is implicit in the foregoing approach that there is no social economic cost to the government introduction of indexed bonds. It is clear, however, that the government has to finance the interest payments on these bonds. The need to finance these payments imposes a cost on the consumers at large, a cost which may (or is likely to) abolish the benefit of the program. Thus, looking both at the costs and the benefits one cannot argue that the introduction of such bonds necessarily improves consumers' welfare. We shall then consider the arguments that a market for linked bonds tends to encourage savings and reduce "inflationary spending" in the economy. An analysis of this proposition within the framework of a specific model supports the proposition concerning savings but is rather indeterminate concerning the effect on the inflationary process.

If the inflationary process is assumed to be exogenous, we may apply the general principle that *laissez-faire*, perfect competitive markets lead to a Pareto optimal allocation of resources and intervention in that process cannot lead to a superior posi-

* Professors of economics, Hebrew University, Jerusalem, Israel.

tion from the point of view of everybody. In this paper we show in a specific model who benefits and who is hurt from the government intermediation.

Moreover, the inflationary process is at least partially created, influenced and produced by government actions. One has to take into account the ability of governments to manipulate and influence the inflationary process itself and therefore the general principle that competitive markets lead to Pareto optimality cannot be simply applied. One has to take into account the different distributional effects of various government measures. Usage of different rules or acts, like inflationary financing and taxation, will have different distributional implications.

## I. The Formal Model

In order to deal with these problems we need a model for individual and government behavior. For the individual we choose a simple model based on two-period planning.[1]

Consider an individual with a two-period planning horizon who consumes a single commodity. We denote his real consumption of the commodity by $c$ and his initial endowment by $y_1$. We also assume that he has an initial endowment of $\overline{M}$ nominal dollars and wishes to hold $M$ dollars, the real value of which yields direct utility as a consumer's good. He may also hold positive or negative amounts of nonlinked or linked bonds. The dollar values of nonlinked and linked bonds are denoted by $B_N$ and $B_L$ respectively. The *gross* nominal rates of return on a dollar invested in nonlinked and linked bonds are denoted by $i$ and $r(p_2/p_1)$ respectively, with $r$ being one plus the real rate of interest on linked bonds and $i$ is one plus the interest rate.

The individual's budget constraint for the first period, in real terms is given by

$$(1) \qquad y_1 - c + \bar{m} - m = b_N + b_L$$

where

$$\bar{m} = \frac{\overline{M}}{p_1}, \qquad b_N = \frac{B_N}{p_1} \quad \text{and} \quad b_L = \frac{B_L}{p_1},$$

$p_1$ being the dollar price of the commodity in the first period. Denoting by $w$ the real value of the individual's wealth in the second period we have

$$(2) \qquad w = (m + ib_N)\pi + rb_L + y_2$$

where

$$\pi = \frac{p_1}{p_2}.$$

Assuming $p_2$ (next period's price) and hence $\pi$, to be the only random variable in the system we obtain the following expression for the expected value of $w$ (denoted $\bar{w}$) and its variance (denoted by $V_w$):

$$(3) \qquad \begin{aligned} \bar{w} &= (m + ib_N)\bar{\pi} + rb_L + y_2, \\ V_w &= (m + ib_N)^2 V_\pi \end{aligned}$$

where $\bar{\pi}$ and $V_\pi$ denote the expected value and variance of $\pi$ respectively.

The expected utility ($U$) function is assumed to be based on the mean-variance approach for the second period and on separability between periods, i.e.,

$$(4) \qquad U = u(c, m) + f(\bar{w}, V_w).$$

In some of our calculations $f$ is assumed to be quadratic

$$(5) \qquad f(\bar{w}, V_w) = \alpha\bar{w} - \beta(\bar{w}^2 + V_w)$$

with $\alpha$, $\beta > 0$ and $\alpha - 2\beta\bar{w} > 0$. The individual is assumed to maximize $U$ with respect to all the decision variables ($c$, $m$, $b_N$, $b_L$) subject to (1) and (3).

The first order conditions with respect to the three independent variables ($c$, $m$,

[1] The model follows closely N. Liviatan and D. Levhari, "Risk and the Theory of Indexed Bonds," res. report no. 67, Dept. of Economics, the Hebrew Univ. of Jerusalem, Mar. 1975.

$b_L$) can be rearranged to read as follows

$$\frac{u_c}{f_{\bar{w}}} = r \tag{6}$$

$$\frac{u_m}{u_c} = \frac{i}{i-1} \tag{7}$$

$$i\bar{\pi} - r = S(m + ib_N); \tag{8}$$

$$S = \left(-\frac{f_{V_w}}{f_w}\right)V_\pi i2 > 0.$$

The first two tangency conditions have an obvious interpretation. The last condition is $(\partial U/\partial b_L)=0$ and it can be stated alternatively as

$$i\bar{\pi} - r = \left(-\frac{f_{V_w}}{f_{\bar{w}}}\right)\frac{\partial V_w}{\partial b_L} \tag{8'}$$

where

$$\left(-\frac{f_{V_w}}{f_{\bar{w}}}\right)$$

is the marginal rate of substitution between $\bar{w}$ and $V_w$, and is positive for a risk averter $[f_{\bar{w}}>0, f_{V_w}<0]$.

Notice that sign $(i\bar{\pi}-r)=$ sign $(m+ib_N)$. This implies that we cannot have a negative risk premium for nonlinked bonds, $i\bar{\pi}-r<0$, because then $b_N<0$ for everybody and no market equilibrium exists. The same is true for $i\bar{\pi}-r=0$. The only possibility which is consistent with both positive and negative $b_N$ is a *positive* risk premium, i.e., $i\bar{\pi}-r>0$.

## II. The Model of Government Intermediation

We shall assume that the purpose of government intermediation in the bonds market is to increase the size of the market for indexed bonds (or to create such a market when originally it did not exist), through the supply of government indexed bonds. This is based on the presumption that the private sector is reluctant to issue indexed bonds. We assume that in order to finance its indexed borrowing the government lends in the nonindexed market (by buying $b_N$). Thus the government acts as an intermediary in the capital market borrowing indexed and lending nonindexed in order to overcome the private sector's aversion to borrow "indexed." Our purpose is to investigate the implications of this intermediation.

A common argument is that by its intermediation the government enables the individuals (or firms) to reach a better diversification of their portfolios. This would indeed be the case if the individual could ignore the government need to finance any possible losses associated with its intermediation agency. If however we take into account the need of the government to balance its accounts associated with the intermediation, we shall realize that no overall improvement in welfare is possible. To calculate the government "profits" from intermediation, notice that it pays on each dollar it borrows $r\cdot(p_2/p_1)$ $(=r/\pi)$ and gets $i$ on each dollar it lends. Thus in real second period magnitudes the agency's profits are $B^*(i\pi-r)$ where $B^*$ is the value of its borrowing (or lending). Let us assume first that the government balances its accounts by paying out (in the form of transfer payments) to the consumers the agency's profits when the rate of inflation is relatively low $(i\pi-r>0)$ and by taxing the consumers to finance its losses when inflation is relatively high $(i\pi-r<0)$. Thus the government operates on the principle of a balanced budget. (We shall consider later the case where the government does not adhere to this principle.) We shall assume that the amount of transfer payments received by a particular individual is independent of the amounts loaned or borrowed by him. Moreover, we assume that the transfer payments do not vary across individuals so that it is equal to $b^*(i\pi-r)$ where $b^*$ is the real per capita value invested in government bonds. The

individuals are assumed to be aware of the system of transfer payments associated with the intermediation. The individuals' wealth constraint can then be written as:

$$(9)\qquad \begin{aligned} w &= y_2 + (m + ib_N)\pi + rb_L \\ &\quad + b^*(i\pi - r) \\ &= y_2 + [m + i(b_N + b^*)]\pi \\ &\quad + r(b_L - b^*). \end{aligned}$$

The second period variance of wealth:

$$(10)\qquad V_w = [m + i(b_N + b^*)]^2 V_\pi.$$

The term $-rb^*$ is the indexed indebtedness of consumers originating from the expected taxation. This debt is equivalent to any indexed loan of size $b^*$. The assumption is that this debt is no different in any respect from indebtedness through bonds, i.e., the consumers in their behavior take into account all the future tax payments. If there has been no market for indexed bonds without the government's intermediation due to some individual aversion, it is intuitively clear that we could not improve their welfare through the introduction of indexed bonds by the government. The *cost* is the simultaneous introduction of indexed indebtedness of the consumers through their future taxes.

We can now show that government intermediation cannot bring about an overall improvement in the allocation of risk. This can be shown as follows. We see from (9) that the government intermediation is equivalent to a new allocation of $b_N$ and $b_L$ among individuals. Thus if we consider an indexed obligation to pay taxes $rb^*$ as equivalent to indexed borrowing, then we may regard $b_L - b^* = \tilde{b}_L$ as "effective" indexed borrowing. Similarly, we may consider $b_N + b^* = \tilde{b}_N$ as effective nonindexed lending. Summing over all individuals we also have $\sum \tilde{b}_L = \sum \tilde{b}_N = 0$. Hence $\tilde{b}_L$ and $\tilde{b}_N$ represent a *feasible* allocation of loans. If this allocation of loans improves the overall welfare, then the original *laissez-faire* allocation was not Pareto-optimal which seems to be a contradiction. In other words, the government intermediation as described above is just a reshuffle of loans and therefore is unlikely to improve upon the competitive allocation.

We argued elsewhere, using the approach of Kenneth J. Arrow and Robert C. Lind, that there does not seem to be a case for *pooling advantages* resulting from government intermediation in indexed bonds. According to Arrow and Lind, an intermediating company of the kind discussed in our paper will act on the basis of expected values, reducing overall risk if at least two conditions are satisfied. First, the variation in the company's profits must be independent of the other profits or incomes of its shareholders. Second, an individual shareholder's dividend from the company should be made negligible compared with his incomes from other sources, by increasing the number of shareholders. This however does not seem to be the case with the problem in question. Note, first, that the intermediating company's profits will fluctuate with the value of money and so will all the nonlinked incomes and assets of the shareholders. Thus the independence assumption is not met. Furthermore, since everybody is involved in the bond market and everybody pays taxes, we cannot make the share of an individual shareholder negligible compared with his other incomes if the company is to handle a large fraction of the loan market in the economy.

We have assumed so far that the government acts on the basis of a balanced budget. Alternatively, the government could act on the basis of an unbalanced budget financing the agency's losses by printing new money and using its profits to reduce the money supply. Thus when inflation is relatively high so that the agency has losses, the government will increase the money supply and when inflation is rela-

tively low so that the agency has profit, the money supply will contract. It follows that the agency will increase the instability of the money supply and therefore also the value of money. Consequently, some consumers will face a reduction in welfare.

In order to see more accurately the implications of deficit financing of intermediation losses, let us use a simple quantity theory approach. Thus let us assume that next period price level changes are proportional to the quantity of money. The quantity of money per capita in the second period is:

$$\overline{M}_2 = \overline{M}_1 + p_2 g - p_2 b^*(i\pi - r) \tag{11}$$

where $\overline{M}_1$ represents the first period per capita money supply, $g$ represents real government deficit (per capita) through its regular expenditures and $-b^*(i\pi - r)$ represents the real losses per capita which are added to the money supply (as it is financed by deficit). Here inflation is endogenously determined and it is determined by real government deficit spending $g$. The inflation path will be induced by $g$ through its impact on the money supply. If $g$ is assumed to be random so will be the implied price level.

The *quantity theory* assumed states that

$$\frac{\overline{M}_2}{p_2} = k \qquad (k \text{ is a constant}). \tag{12}$$

Combining (11) and (12) and using

$$\pi = \frac{p_1}{p_2},$$

we obtain

$$\pi = \frac{k - rb^* - g}{\bar{m} - ib^*} \tag{13}$$

where

$$\bar{m} = \frac{\overline{M}_1}{p_1}.$$

The expected value and variance of $\pi$ are given by:

$$\bar{\pi} = \frac{k - rb^*}{\bar{m} - ib^*} + \frac{1}{ib^* - \bar{m}} \bar{g} \tag{14}$$

$$V_\pi = \frac{1}{(\bar{m} - ib^*)^2} V_g. \tag{15}$$

We assume that $ib^* < \bar{m}$ which means that the private nonindexed liability to the government in the next period is less than the original money supply. In this case, an increase in $b^*$ leads to an increase in $V_\pi$.

Consider again the "experiment" described earlier where the government intermediation leaves $b_N$ of borrowers constant (shift from private to government borrowing) and reduces lenders' $b_N$ (shift from nonindexed to indexed lending) leaving everyone's $\bar{w}$ unchanged (by setting $r = i\bar{\pi}$). The variance of second wealth is

$$V_w = (m + ib_N)^2 V_\pi.$$

In the case of borrowers, $V_w$ will increase as a result of our increase in $V_\pi$ (through an increase in $b^*$) causing a reduction of welfare. As for lenders ($b_N > 0$) $b_N$ will decline while $V_\pi$ will increase leading to compensated changes or changes in different directions in their welfare. In any case some consumers will be made worse off by the government intermediation.

Of course, in reality the restrictions of the foregoing "experiment" are too tight and the situation is more complicated. For example, the introduction of $b^*$ will affect not only $V_\pi$ but also $\bar{\pi}$ and has additional effects on welfare. If we calculate the difference ($\Delta\bar{\pi}$) between the value of $\bar{\pi}$ with $b^*$ and without, we obtain after some manipulation

$$\Delta\bar{\pi} = \frac{k - rb^* - g}{\bar{m} - ib^*} - \frac{k - g}{\bar{m}} = \frac{b^*(i\bar{\pi}^* - r)}{\bar{m}} \tag{16}$$

where $\bar{\pi}^*$ denotes its value *with* $b^*$. Whatever the sign of $\Delta\bar{\pi}$ (i.e., of $i\bar{\pi} - r$), it will affect different consumers in different

ways. Thus if $\Delta\bar{\pi}$ is positive, it will tend to improve the lenders' welfare and reduce the welfare of large borrowers as it increases the value of their real debts.

In any case since the increase in $V_\pi$ will diminish welfare for a large section of the consumers, we see that a change from the mode of operation of the agency from direct taxation to deficit financing does not change drastically the conclusions.

### III. The Impact of Governmental Intermediation on Consumer's Portfolio and Savings

So far we have considered government intermediation from the point of view of improving the allocation of risk in the economy. There are however other arguments which are in favor of linked bonds. One such argument states that the introduction of governmental linked bonds tends to encourage personal savings in inflationary times. Another argument concerns the *composition* of savings, or of consumers' portfolio. In particular, it is argued that linked bonds tend to channel investment which would otherwise take the form of investment in real assets as a hedge against inflationary uncertainty. Thus the introduction of linked bonds enables the economy to avoid real investment which is directed to the sole purpose of inflationary hedging.

In order to analyze the foregoing arguments, we have to extend our model and include in it a physical asset which may serve as a substitute for linked bonds. We cannot ignore however the fact the investment in real capital has risks of its own. Let us introduce accordingly a physical productive commodity with a random return of the variety of "technological uncertainty." For simplicity, we take this commodity to be identical with the commodity consumed ("wheat"). The quantity of "wheat" held as a productive asset will be denoted by $q$ $(q \geq 0)$ and its gross rate of return (in physical units) will be denoted by $x$. We assume that $x$ is a random variable with a known distribution. The individual's $w$ is then

$$(17) \qquad w_N = (m + ib_N)\pi + qx + rb_L; \qquad b_N = u - c + \bar{m} - m - q - b_L$$

with $\bar{w}$ and $V_w$ given by

$$(18) \qquad \bar{w}_N = (m + ib_N)\bar{\pi} + q\bar{x} + rb_L$$
$$V_{wN} = (m + ib_N)^2 V_\pi + q^2 V_x + 2q(m + ib_N)\,\mathrm{cov}\,(x, \pi).$$

Let us consider now the effect of introducing governmental linked bonds, by means of intermediation, when no such market exists or enlarging the size of an existing market for linked bonds when it is considered to be too small. To analyze the effects of this policy in a framework of general equilibrium seems to be at this stage too presumptuous. We shall confine ourselves instead to a simple experiment on the micro level which may nevertheless provide some clues as to the result of the (missing) market experiment.

The individual experiment is the following. Consider a consumer who reaches his optimum with respect to the variables $c$, $m$, $q$, $b_L$ and $b_N$ at given interest rates and prices ($i$, $r$ and $p_1$) and a given distribution of $\pi$ (this includes the case where no market for $b_L$ exists in which case $b_L \equiv 0$). Let the optimal values of $b_N$ and $b_L$ be denoted by $b_N'$ and $b_L'$. Let us now change the role of $b_N$ and $b_L$ from decision variables to parameters and change arbitrarily the composition of bonds in favor of linked bonds holding their sum constant (i.e., $b_N + b_L = b_N' + b_L'$). Clearly the change imposed on the composition of bonds will require an adjustment in the optimal quantities of $c$, $m$ and $q$. Our purpose is to inquire into the nature of the latter changes which are caused by the increase in the share of linked bonds in the overall portfolio. This experiment may be considered as a method of finding out which of the variables—$c$, $m$ and $q$—are substitutes and which are

complements of $b_L^1$ as the degree of bond linkage is increased. It may therefore provide some indication as to the result of increasing $b_L$ through government intermediation.

The calculations on the effect of increasing $b_L$ (at the expense of $b_N$) on current consumption ($c$) shows that $(dc/db_L)<0$ (as the sign of $r-i\bar{x}$ is negative), so that more indexation in the bond market discourages current consumption and encourages saving. It is somewhat surprising that with all our simplifying assumptions we did not obtain a definite effect on $q$ and $m$. Thus it is not at all clear whether the introduction of linked bonds will reduce investment in physical assets. The reason for this seems to be that not only the real value of money is subject to variation, because of $\pi$, but also the real asset, because of $x$. In a market equilibrium the relative return on these two assets ($u_m$ being the return on money) are adjusted to compensate for the differences in variances and it is not at all clear a priori which of these assets (if any) should be reduced as $b_L$ increases. The only fact which is clear is that $m+q$ will increase since this is the counterpart of the reduction in $c$.

However in the case of $m$ we find that

$$\frac{dm}{db_L} > 0$$

if the condition

$$V_\pi > (\bar{x} - \bar{\pi})\frac{(i\bar{\pi} - r)}{i} \tag{19}$$

is fulfilled.[2]

The results of our experiment seem to indicate the following consequences of introducing linked bonds: a reduction in expenditures on current consumption, an indeterminate effect on investment in physical capital, a decrease in *aggregate* demand for physical commodities (consumption plus capital goods) provided the variance of the value of money is sufficiently large.

A related problem which we analyzed was to compare the effect of an increase in $V_\pi$ in two alternative systems, the first without indexed bonds (nonmixed system) and the second with a "mixed" portfolio including $b_L$.

For the reaction of the mixed and nonmixed regimes to an increase in the variance of the value of money ($V_\pi$) we have the following conclusions. If there is a considerable variability in the returns on physical investment (which is a reasonable assumption), then an increase in $V_\pi$ will increase the demand for current consumption in the nonmixed regime and reduce it in the mixed one. *Demand* for investment in physical assets will increase under both regimes but the increase is likely to be greater under the nonmixed regime. (This is likely to be the case when physical assets and linked bonds are substitutes in the sense defined earlier.) It is not clear whether the current inflationary pressure resulting from an increase in $V_\pi$ will be smaller in the mixed regime. This is related to the fact that there does not seem to be a tendency for a flight from money (and into commodities) under the nonmixed regime.

The main advantages of mixed regimes seem to lie in the tendency of this regime to keep the demand for current consumption and investment in physical capital at relatively lower levels under the conditions specified earlier. If this is considered as an advantage, then it is achieved at the cost of a relatively inefficient allocation of risk in the economy.

[2] A possible intuitive explanation may run as follows. By supplying more "indexing," i.e., by increasing $b_L$ relative to $b_N$, we provide him with more safety as far as changes in $\pi$ are concerned. He may afford, therefore, to enjoy more liquidity in spite of the risk associated with it.

# Inflation and the Income Tax

By HENRY AARON*

'Tis the Night Before Xmas, and all through the nation
Your bonus means nothing because of inflation.[1]

The recent increase in inflation has elevated the question of whether and how the tax system should be adjusted to cope with rising prices from a matter of academic curiosity to a live political issue. Many other nations, having long experienced high rates of inflation, years ago adopted rules for altering their tax systems automatically as prices rise. Should the United States do so today? If so, what adjustments should be made automatically, and which should be left to *ad hoc* remedy by periodic legislation?[2]

## I. The Problem

Inflation affects tax liabilities in three ways. First, it may alter real factor incomes. Second, it affects the measurement of taxable income. Third, it changes the real value of deductions, exemptions, credits, ceilings and floors, bracket widths, and all other tax provisions legally fixed in nominal terms.

Inflation affects factor incomes by altering such quantities as nominal interest rates, desired money balances, real tax collections (due to inflation-causing issuance of money), and savings. In short, inflation may alter the comparative static general equilibrium and necessitate lengthy adjustments. Whether taxes are collected on nominal incomes, real incomes, or some combination, will affect the properties of the resulting general equilibrium and may have perceptible effects on economic efficiency and on pretax income distribution. Unfortunately, current understanding of these issues is primitive.[3] Whether or not the tax code *should* be written to take account of inflation may well depend on the nature of these effects. However, one must first understand the adjustments necessary to convert the income tax from a tax on nominal income into a tax on real income. In general, the tax code properly disregards the forces that generated income; it is concerned only with measuring correctly the income actually received.

## II. A "Real" Income Tax: Income Definition

All business income may be regarded as the excess of gross receipts (or sales), $S$, over a set of expenses including labor costs —$L$, material costs—$M$, depreciation—$D$, and interest costs, equal to the product of the market interest rate, $r$, times net debt —$B$.[4] Profits, $\pi$, are thus

$$\pi = S - (L + M + D + iB),$$

where $r = i$ the real interest rate in a world of stable prices.

[1] *Mad Comics*, no. 172, Jan. 1975, p. 11.

[2] These questions were examined at a recent conference sponsored by the Brookings Institution and the Fund for Public Policy Research. This paper draws freely from the Conference papers and discussion, which will be published by Brookings in 1976. My acknowledgments to participants are too extensive and too numerous to list, as readers of the forthcoming book will find obvious.

[3] For pioneering efforts see Martin Feldstein (1975b) and Jerry Green and Eytan Sheshinski (1975).

[4] For simplicity, I assume that borrowing and lending rates are identical.

*I define a "real" income tax system to be one that imposes the same real tax burden on any given real transactions regardless of the rate of inflation, $\dot{p}$.*[5] Thus, taxable income from capital must be $\pi(1+\dot{p})$ for any value of $\dot{p}$. In addition, all nominal quantities in the tax code must be inflated by $\dot{p}$, so that their real value is unchanged.[6]

The current tax system clearly does not tax real income. Four changes are necessary. Assume that all prices rise proportionately. Interest rates rise enough to keep real interest payments, measured in current dollars, constant, $i(1+\dot{p})$, and to offset the decline in the nominal value of net debt, $\dot{p}B$, i.e., $r=[i(1+\dot{p})+\dot{p}]$. If the firm uses FIFO accounting, profits, $\pi'$, are given by

$$\begin{aligned}\pi' &= (S-L)(1+\dot{p}) \\ &\quad - \{M+D+(i(1+\dot{p})+\dot{p})B\} \\ &= (S-L-iB)(1+\dot{p}) \\ &\quad - (M+D+\dot{p}B)\end{aligned}$$

Profits are misstated by

$$\pi' - \pi(1+\dot{p}) = \dot{p}(M+D-B)$$

This equation underscores three of the four adjustments necessary to make real taxable income independent of inflation. First, inventory costs must be inflated by the increase in the general price level. Second, depreciation must be similarly adjusted.[7] Third, the firm must be taxed on the capital gain arising from the decline in the real value of net debt, $\dot{p}B$. In that case, profits are equal to

$$\begin{aligned}S(1+\dot{p}) &- L(1+\dot{p}) - D(1+\dot{p}) \\ &- [i(1+\dot{p})+\dot{p}]B + \dot{p}B \\ &= [S-(L+M+D+iB)](1+\dot{p}) \\ &= \pi(1+\dot{p}).\end{aligned}$$

In plain English, a "real" tax system requires that the historical cost of materials and of depreciation be increased by the rate of inflation and that the capital gain on the decline in the real value of net debt be included in taxable income.[8]

The fourth adjustment concerns capital gains. If prices rise 100 $\dot{p}$ percent per year and assets appreciate 100 $r$ percent per year, nominal growth will be 100 $n$ percent ($n=r+\dot{p}$). After t years an asset purchased at 1 will be worth $e^{nt}$, the original purchase price in current dollars will be $e^{\dot{p}t}$, and the real gain in current dollars will be $(e^{nt}-e^{\dot{p}t})$. This amount should be included in taxable income.[9]

Two observations are in order. First, the market interest rate may not rise exactly to $i(1+\dot{p})+\dot{p}$. In that case the real interest cost changes. But many factors in addition to inflation can cause changes in real interest rates. If the objective of the tax system is to impose the same real tax burdens on given real transactions regardless of the price level, then tax burdens should be altered by changes in real interest rates

[5] I assume the initial price level is unity and ignore the choice of an appropriate index with which to deflate the various entries used in calculating income.

[6] An alternative definition of a real tax system would require that real after-tax income be unaffected by inflation. I find this goal overambitious and hard to define. It would require the tax system to offset effects on real factor incomes. And, since the supply of labor might be effected, it would require valuation of leisure.

[7] I assume that the value of depreciable assets is expressed in prices prevailing at the beginning of the accounting period. This assumption is equivalent to assuming that the book value of assets is adjusted annually by $\dot{p}$. Alternative adjustments that defer taxation of gains and losses from changes in relative prices are allowance of *LIFO* inventory accounting and replacement cost depreciation.

[8] John B. Shoven and Jeremy Bulow have argued that if accrued gains on net debt are included in income, the decline in the market value of net debt should also be included. Thus, if bonds decline from 100 to 80 because interest rates rise, a firm should include 20 percent of its net debt in income, since it could repurchase its debt and realize a profit. Although this suggestion has some theoretical appeal, practical objections to it are enormous.

[9] Roger Brinner has shown that if half of capital gains are subject to tax in a world of stable prices, the proportion of capital gains subject to tax when prices are rising is less than half, but approaches half as the holding period increases, i.e., $.5\,(e^{nt}-e^{\dot{p}t})\,/\,(e^{nt}-1)$.

Table 1—Change in Tax Liability as Percent of Before Tax Income if Full Adjustment for Five Percent One-Time Inflation were Introduced

| | First Year and Long-Term Effects[a] | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Manufacturing, Mining Construction | | Transportation, Communication, Electric, Gas Services | | Wholesale and Retail Trade, Services | | Finance, Insurance Real Estate | |
| | First Year | Long Term | First Year | Long Term | First Year | Long Term | First Year | Long Term |
| Change in Taxes | (percent of firms) | | | | | | | |
| *Decline* | | | | | | | | |
| More than 100% | 1.1 | 2.8 | 0 | 4.9 | 0.7 | 2.9 | 6.3 | 7.9 |
| 50–100% | 0.8 | 4.1 | 0.1 | 6.5 | 0.7 | 3.4 | 7.4 | 8.8 |
| 20–50% | 3.7 | 11.7 | 1.6 | 15.8 | 2.9 | 12.0 | 18.2 | 19.9 |
| 10–20% | 4.9 | 16.8 | 1.5 | 16.6 | 4.5 | 16.2 | 13.5 | 13.5 |
| 0–10% | 36.7 | 49.6 | 16.2 | 35.4 | 28.6 | 46.9 | 15.0 | 15.6 |

[a] Tax liabilities are discounted at 5 percent.

whether caused by inflation, changes in money supply, or "animal spirits."

Second, inflation adjustment may raise or lower tax burdens. The more heavily leveraged a firm is, the more likely is its tax burden to be increased during the onset of inflation by the introduction of inflation adjustments. The size of the debt adjustment depends only on the amount of current inflation. But the size of the adjustment for depreciation depends on the amount of inflation since the oldest depreciable asset was acquired. Thus, the depreciation adjustment begins slowly and, in the face of protracted inflation, only reaches its maximum after many years. T. Nicholas Tideman and Donald Tucker have demonstrated this fact for *U.S.* corporations with assets exceeding $1 million. (See Table 1.) Most firms would pay more tax under a real income tax system than they do under the existing system with the onset of inflation. Large, and in some cases dramatic, tax increases for utilities are the rule because typically they are heavily leveraged. The reverse pattern prevails for financial corporations. Long-term tax burdens are reduced for the overwhelming majority of firms and most dramatically for utilities, a highly capital intensive industrial group. This reversal occurs because heavily leveraged firms, that suffer tax increases from indexation at the onset of inflation, tend to have long livid capital assets and to benefit greatly from revaluation of depreciable assets.

The most striking aspect of Table 1, however, is the extreme variety of impacts of a switch to a real income tax system. A sizeable redistribution of business income tax liabilities would occur.[10]

[10] Sidney Davidson and Roman Weil have calculated the first year effects of these adjustments for the Dow Jones 30 Industrials and 24 Utilities. Their results confirm the wide range of effects. *AT&Ts* taxable income for example, would have risen from $2.490 billion to $4.639 billion in 1974 based on reported transactions. By contrast taxable income of General Motors would have fallen from $1.065 billion to $.254 billion.

### III. A Real Income Tax System: Nominal Quantities

Once income has been defined, actual tax liabilities are calculated by applying tax rates, exemptions, credits, allowances, and deductions, in order to reach taxable income and tax liability. Many of these provisions are expressed in fixed nominal amounts.[11] The real value of those and other magnitudes is reduced when prices rise. Through this channel inflation unambiguously increases income tax liabilities on both individuals and corporations.

According to estimates by Emil H. Sunley and Joseph A. Pechman, the combination of inflation and growth would have increased personal income tax collections from 10.7 to 16.3 percent of adjusted personal income between 1960 and 1975 if Congress had not modified income tax laws. Real growth alone would have increased revenues from 10.7 percent to 12.3 percent of adjusted personal income. In fact, personal income taxes rose from 10.7 to 11.4 percent of adjusted personal income, between 1960 and 1975, indicating that tax changes enacted periodically by Congress counteracted not only the increase in revenues generated by the impact of inflation on the rate structure, but also part of that caused by real economic growth.

The composition of the discretionary tax reductions differed slightly from the reductions that indexation of the rate structure would have generated. In particular, discretionary tax changes have reduced taxes more than indexation would have done for those with real incomes in 1975 dollars below $25,000 and over $200,000, and have reduced them less for those with incomes between $25,000 and $200,000. The difference in disposable income is less than 1 percent for those with incomes of $10,000 to $25,000.

A long-standing argument against indexation of nominal quantities has been that a rate structure fixed in nominal terms acts as a built-in stabilizer. When prices rise, real tax collections increase, dampening aggregate demand and thereby curtailing inflationary forces. This argument is incomplete, however. If inflation and excess unemployment coexist, the reduction in aggregate demand caused by the inflation-generated increase in taxes will tend to stabilize the price level, but aggrevate unemployment.

Based on simulations performed on the SSRC-MIT-PENN model, James Pierce and Jared Enzler report that the impact on real and nominal economic aggregates of an exogenous increase in demand is affected negligibly by indexation of the nominal quantities in the personal income tax.[12]

### IV. What Should Be Done?

> A government's decision as to elimination of each of the two types of inflation effect is logically independent of its decision with respect to the other. It may choose to index the tax system so as to tax income expressed in prices of some former year instead of income in current prices however the latter may be measured; to eliminate distortions in the measurement of income in current prices; to do neither of these things; or to do both of them. [Edward Denison]

Because the choice about what to do involves guesses about the outcome of research not yet performed and political judgments on which we are all amateurs, I shall try to characterize the views expressed at the Brookings Conference and turn to my own only in conclusion.

[11] For example, in 1975 married couples paid 14 percent of the first *$1,000* of taxable income in tax; the personal exemption was *$750;* the per capita credit was *$30;* corporations paid 20 percent on the *first $25,000* of profits, and 22 percent on the *second $25,000*; the low income allowance was *$1,900* and the maximum standard deduction was *$2,600*.

[12] In correspondence, Ray Fair reports similar results for identical simulations in his model.

Few thought that indexation of nominal quantities (i.e., of the rate structure) was intrinsically very important at rates of inflation experienced since 1960 or even since 1970. Congress has shown itself quite capable of reducing taxes sufficiently promptly to keep aggregate collections roughly constant. The difference between discretionary tax cuts and the hypothetical results of an indexed 1960 law may be viewed either as expression of a collective desire to reallocate tax burdens or of irrational Congressional reticence to tamper with the divisive issue of the rate structure. But, in either case, the difference is small. (Actual reductions have concentrated on personal exemptions, the standard deductions, low income allowance, maximum tax on earned income, the personal credit, the earned income credit, and so on.) The differences between the stabilizing properties of an indexed system and those of a periodically amended system are negligible.

In the eyes of those who place primary emphasis on indexation of the measurement of income, indexation of the rate structure was viewed by some as likely to further their primary goal (by alerting policy makers to the issue) and by others as likely to impede their primary goal (by letting the public think that partial action was enough). According to another view, indexation of the rate structure would set back the cause of tax reform. Tax reforms typically increase revenue by widening the base, but Congress seems loathe to enact revenue-increasing tax bills. Consequently, tax reform is most likely to occur when automatic increases in revenues create the opportunity for discretionary reductions. Indexation would drastically reduce the number of such opportunities.

While these judgments are clearly open to challenge, the key point is that no participant at the Brookings Conference argued that indexation of the rate structure is very important and all felt that the issue is primarily political, not economic.

The case for or against the tax base is far more complex and rests to a much greater extent on economic analysis. Unfortunately, much of that analysis has not been done. The basic argument for indexation of the tax base flows naturally from modes of analysis congenial to economists. First, all of the postulates of welfare economics rest on marginal equalities among real quantities. If taxes fall on nominal quantities that are not proportional to real quantities, excess burdens result. Second, a nominal tax system violates principles of horizontal equity and may increase the volatility of interest rates during inflationary periods. Balancing these advantages of a real income tax system are the added compliance costs for business and households. At 30 percent inflation, most would feel that benefits of a real income tax system outweighed added compliance costs; at 1 percent inflation the reverse is true. The practical question, then, is how much inflation makes adjusting the tax base worth the added trouble. If a decision is made to adjust the tax base, how should it be done, and how quickly?

The latter question gains force from the estimates compiled by Tideman and Tucker, summarized in Table 1. They suggest that the redistribution of tax liabilities among and within industries, in both the short and the long run, from even a short burst of inflation would be sizeable. The effects of sustained inflation would be even greater. While the distortions of a nominal tax system have little to recommend them, many may have been capitalized into equity prices. Their removal would create windfall gains and losses, perhaps large ones. This possibility suggests the need to consider how an indexed system should be introduced.[13] This issue was raised, but not

[13] Should it be enacted now, but become effective only after several years? Should taxpayers be required

addressed, at the Brookings Conference.

Furthermore, all taxes create distortions and excess burdens. Under a nominal tax system, inflation changes those distortions. But it is not clear which set of distortions is more serious.[14] Consider the following argument. "In the absence of inflation, income from capital is undertaxed, largely because only half of capital gains is included in income, the interest on state and municipal bonds is exempt, and businesses may claim excessively rapid depreciation (especially on structures, see Paul Taubman and Robert Rasche) and the investment tax credit.[15] Inflation operates through a tax system based on historical cost in the same manner as an imperfect capital levy (see Peter A. Diamond). Accordingly, inflation at least up to some (what?) level offsets existing imperfections in the definition of income." If this view is accepted, then adjustment of the tax base for inflation may be desirable only as part of a general reexamination of the taxation of income from capital.

Some participants in the conference held that indexation should reproduce the real tax burdens in an inflationary world that the *present* tax code would generate if prices were stable. I find this view untenable. First, some existing provisions were introduced or are retained in part to offset inflation. (Abandonment of the reserve-ratio test seems the clearest example.) Second, the view that removing the distortions of inflation deserves attention whether doing so aggravates or ameliorates existing imperfections seems to place form before substance.

## V. Conclusion

The most useful conclusion I can offer to this incomplete treatment of the issues surrounding indexation is an agenda for future research, however partial and idiosyncratic it may be. First, models of the effects of inflation through the tax system on the real equilibrium and on the growth path of the economy are in an early stage of development. Until we have a better understanding of how the failure to index affects real quantities, it is hard to argue persuasively that conversion to a "real" income tax is worth the legislative trouble, the probability that a radically new approach to taxation will entail costly and lengthy shakedown period, and the further erosion of the simple, nominal dollar standard we live by (see Arthur Okun). Although this research is important, it is immensely complicated and so far has required drastic and essentially important abstractions from reality if any analytic results are to be obtained. For this reason, I am pessimistic that it will contribute much *independently* to the debate about indexation.

Second, extensive research on problems of transitional equity is clearly indicated and is likely to contribute significantly to the policy debate. How great are the dislocations of switching from the existing tax system to an indexed one? Who gains? Who loses? How can losers be compensated? Should they be? Clearly these estimates must entail models of the impact of inflation on real quantities under a "nominal" income tax system.

Finally, a whole set of questions relating to administrative costs (a low prestige subject which economists of even moderate ambition discreetly ignore[16]) need to be examined. Is the added cost of an inflation adjusted system big or small? If it is big,

---

to calculate liabilities under both nominal and inflation-adjusted bases, and pay tax on a weighted average, where the weights shift over time? Is some other course preferable? On transitional equity, see Feldstein (1975a).

[14] See Martin Bailey.

[15] This argument presumes that income, rather the consumption, is the proper tax base.

[16] A notable exception, but only at the theoretical level, is Walter Heller and Karl Shell.

are there short cuts to indexation that remove most of the distortions but cause few of the adjustment problems? Precisely what changes must be made to index the tax system?

When the answers to some of these questions are available and when we are better able to tell whether the inflation of the past few years was an unwelcome intruder or the harbinger of an inflationary brave new world, we will be in a better position to determine the desirability of indexation. Until then, I suggest that we recall Mort Sahl's definition of a "modern Republican," a person who is willing to try new policies —but not now, and that we adopt the mantle of "modern indexers."

# Indexing and the Capital Markets

By WILLIAM POOLE*

The inflation of the past few years has generated substantial interest among economists in the theory of price level indexed bonds. But this academic interest, as measured by the number of papers on the subject, stands in sharp contrast to the market interest in indexed bonds as measured by the number of new issues of such bonds. Indeed, a recurring theme in recent papers on indexing is the question of why indexed bonds do not exist in the United States.

The analysis of the nonexistence of indexed bonds, and of the potential role of these bonds more generally, may be conveniently divided into four topics, and this paper is organized accordingly. The first topic concerns the analysis of indexed bonds within the context of a total portfolio. The second concerns the role of indexed bonds in changing the economy's response to changing rates of inflation. The third concerns the use of these bonds to eliminate the distortion to the time shape of debt service caused by inflation. The fourth topic—one given insufficient attention in my view—concerns the practical problems of index construction and related matters.

## I. Portfolio-Theoretic Analysis

The recent application by Stanley Fischer (1975a, 1975b) and others of standard portfolio theory to index bonds has substantially improved the analysis of these instruments. It is now generally accepted that, roughly speaking, the household demand for indexed bonds—a demand that may be negative if bonds are issued as a source of funds—depends on how the bonds fit into a total portfolio consisting of human and physical capital, equities, nominal bonds, and nominal debt. Similarly, a firm's supply of indexed bonds—a supply that also can be either positive or negative—depends on how such bonds fit into a capital structure consisting of nominal bonds and equities financing the real and/or financial assets owned by the firm. In the abstract, the same portfolio theory is applied to households, financial firms, and nonfinancial firms and these different types of economic units take on separate theoretical identities according to the assumptions made about the expected yields and the variances and covariances of the yields on the different types of assets and liabilities. Of lesser importance, the different types of economic units may also be assumed to differ in their attitudes toward risk.

Alan Blinder (1975), using a portfolio model, has recently suggested that indexed bonds do not exist because a firm would want to choose as the index the price of its own output while a household would want a general price index. Blinder's ingenious solution to this problem is his proposed "National Inflation Mutual Fund" that would buy bonds indexed to individual industry prices and sell bonds indexed to a general price index. As Blinder emphasizes, however, a firm would want to issue bonds indexed to its own selling price only if that price were positively correlated with the firm's profits. A firm would not want to issue such bonds if cost-push forces frequently forced up its own prices and simultaneously reduced its profits.

Blinder's cost-push argument can be

* Professor of Economics, Brown University.

generalized; I would conjecture that *U.S.* experience has been for inflation surprises to be associated with lower real yields on human and physical capital independently of whether the inflation is higher or lower than anticipated. On the one hand, inflation lower than anticipated has usually been associated with business cycle downturns and, therefore, with reduced returns due to unemployment of labor and capital. On the other hand, inflation higher than anticipated has typically occurred during or just after wars. War absorbs part of the national output and leaves less output available to serve as the real return to labor and capital.

The cost-push argument emphasized by Blinder—applied, for example, to the effects of poor harvests and the Organization of Petroleum Exporting Countries (*OPEC*) cartel on inflation in 1973–74—may or may not provide a satisfactory explanation for the recent inflation; there is still the question of whether the cost-push disturbances would have had much effect in the absence of a prolonged period of above-normal money growth. But whatever the merits of the various theories of inflation, if it is true that unanticipated accelerations of inflation are correlated with reduced supplies of domestically available goods, then it is clear that issuance of indexed bonds, whether linked to general or industry prices, will not be attractive to firms. On this view the standard portfolio models suffer from a symmetry assumption, the assumption being that if equity-type investments have real yields that are affected by inflation, then those yields change in one direction when inflation is higher than anticipated and in the opposite direction when inflation is lower than anticipated.

An observation supporting my conjecture is that long-term corporate bonds almost without exception are callable well before maturity. I have recently collected data on all *A*aa and *A*a long-term (20 years and over) corporate bonds issued in the United States from 1965 to mid-1974; of my sample of 535 issues, only two were noncallable to maturity and none of the others had more than 10 years of call protection. For no bonds were the call premiums very large. Similarly, individual home mortgages typically have very limited call protection. The callable bond and callable mortgage are well-designed instruments for economic units whose real earnings are depressed by inflationary surprises in both directions; real interest costs fall with positive unanticipated inflation but rise only to a limited extent with negative unanticipated inflation because interest rates fall and high nominal interest bonds and mortgages are called and refinanced.

From the recent work it is clear that portfolio theory does not adequately explain the complete nonexistence of indexed bonds in the United States. While it may or may not be true that the representative household and representative firm face parameter values that make indexed bonds unattractive, it must be true that there are many nonrepresentative households and firms for whom indexed bonds would be highly desirable. A diversity of products tailored to different tastes and technology is the rule in competitive markets, and certainly the existing diversity of financial assets suggests that there is no reason why indexed bonds should not have at least some place in the market.

## II. Macroeconomic Performance Under Changing Inflation Rates

It has been argued, especially by Milton Friedman (1974), that widespread indexation would substantially ease the transition to a secularly lower inflation rate and thereby improve the odds that the government will maintain policies consistent with ending inflation. The argument is that

unanticipated declines in inflation cause unemployment because real wages and real debt service rise. Moreover, indexation of the tax structure would eliminate the government's easy access to real revenue through inflation.

Whatever the merits of this position in general, its applicability to the capital markets seems somewhat limited. As noted above, corporate bonds and home mortgages are already rather effectively indexed on the downside through call provisions. The federal government is not especially vulnerable to lower inflation with respect to the real burden of its debt because it has so little long-term debt outstanding and because of its extensive taxing and borrowing capacities. State and local governments are by far the most exposed issuers of long-term debt; municipal bonds are generally not callable and a substantial quantity of debt with distant maturities is outstanding.

### III. The Time Shape of Debt Service

Much recent work on the home mortgage market has emphasized that the traditional fully-amortized fixed rate mortgage carrying a nominal interest rate reflecting inflationary anticipations is a poor instrument for the typical household.[1] The traditional mortgage has a constant nominal debt-service stream and, therefore, a declining real debt-service stream in an inflationary period. If two mortgages, one issued in an inflationary environment and one in a noninflationary environment, have the same anticipated real rate interest, then the one issued in the inflationary environment may involve such rapid repayment in real terms that the typical household may be unable to meet the repayment schedule even though the household's real income prospects are fully adequate to meet the longer real repayment schedule in a noninflationary environment. Other borrowers, such as nonfinancial firms and state and local governments, may face a similar problem.

Many borrowers are able to adjust their borrowing and lending behavior using traditional debt instruments in such a way that the time shape of real debt service of a portfolio package is not changed by inflation. But if real income, real spending flows, and real debt service are to be unaffected by inflation, then during an inflation the portfolio package required to finance a given capital project necessarily involves a larger accumulation of debt, both nominal and real, in the early years of the life of the project; the present value of the distant real debt service must be represented by a currently large value of the principal of nominal debt.

The shortening of the effective maturity of the debt when conventional debt instruments are used in an inflationary period makes all borrowers more vulnerable to bankruptcy. The problem is compounded by the fact that lenders typically do not realize that conventional accounting practices can seriously distort the reported income position of a given borrower. The inflation premium part of nominal interest payments is actually repayment of principal rather than real interest expense.

The use of price level indexed bonds and mortgages would prevent inflation from shortening the effective maturity of debt and would, therefore, reduce the real distortions caused by inflation. In the absence of indexed securities the market has, however, produced some imperfect substitutes for indexed securities, substitutes in the form of adaptations of conventional instruments. The clearest example is the use of the so-called "equity-kicker" clause in commercial mortgages in return for a lower nominal interest

[1] See especially Poole (1972), Donald Lessard and Franco Modigliani (1976).

rate. This provision gives nominal debt service an upward tilt over time, reducing the effect of inflation in speeding up real debt repayment. But market adjustments are surely incomplete; few lenders yet understand the appropriateness in an inflationary period of borrower plans calling for a prolonged rise in the nominal debt outstanding to finance a given capital project.

### IV. Practical Problems with Indexed Bonds

The practical problems of selecting an appropriate index are well-known. These problems, however, are minor compared with the problem that contracts with indexing provisions are much more susceptible to tampering than contracts defined solely in nominal terms. In Israel, many securities issued in the early 1950's were linked to the exchange rate of the dollar, but the indexing provision became worthless due to the government maintaining the official exchange rate at artificially high levels. Later, following linkage to the Israeli Consumer Price Index, there was extensive political controversy over the use of government subsidies to hold down the index and over the construction of the index itself.[2] The index construction problem is much less serious with indexed wages than with indexed bonds because wage contracts are renegotiated at relatively frequent intervals.

The practical problem with indexed securities goes well beyond the possibility of government tampering. The deeper problem is that public attitudes as expressed through democratical political and legal processes provide little protection to indexed contract provisions. Recent experience with wage and price controls in the United States and elsewhere involved governmental cancellation of private contract provisions calling for increases in nominal wages and prices. These cancellations did not meet with any significant opposition; indeed the introduction of controls has generally received overwhelming public support.

At the same time, recent wage-price control experience clearly demonstrates the strength of attitudes involving nominal magnitudes. Freezes have generally commanded widespread support while wage and price rollbacks have received relatively little support. Whatever the reasons for, or rationality of, these public attitudes, they are important and persistent. Given the potential for manipulation of indexes and given public attitudes toward the enforcement of contracts, it is not surprising that indexed bonds have not yet appeared in the United States. No investor can have much confidence that the real yields promised by indexed securities would be realized in the face of a significant escalation of inflation.

### V. Concluding Comment

My guess is that should indexing become popular in the United States the reason will not be the triumph of economists' ideas. Rather, widespread indexing will reflect fundamental changes in the economic environment and in perceptions of the environment. Monetary instability uncorrelated with real shocks will change the variance-covariance properties of different types of assets and make indexed bonds more attractive. With sufficient price level instability, the benefits of indexed bonds will exceed the costs imposed by the practical problems, and public attitudes will force changes in the political environment so that more emphasis will be placed on real magnitudes. Successful innovation of indexed bonds will deserve one cheer—three cheers for indexing plus

[2] See A. Rubner (1960).

two negative cheers for the monetary instability responsible for the event.

# ECONOMIC STATUS OF WOMEN IN INTERNATIONAL WOMEN'S YEAR

# The Economic Status of Women in the United States

*By* MARY DUBLIN KEYSERLING*

International Women's Year (*IWY*)—1975— has provided an extraordinary opportunity for stock taking with respect to where women are in the American economy, where they aren't, and where they ought to be. It has helped focus national attention on the many barriers which still impede the full contribution of women; it has intensified commitment to needed action.

Today, some 38 million women, aged 16 and over, are in the American civilian labor force. The number of female workers has more than doubled since 1950 and has nearly tripled since 1940—one of the most far reaching social and economic transformations of our history. As of October 1975, 47 percent of all women, 16 and over, were in the civilian labor force, as compared with 33 percent in 1950 and 29 percent in 1940. (Of all women aged 18–64—a more meaningful base—the proportion of those in the labor force is now 55 percent.)

Between 1950 and 1974, the total labor force grew by 29 million. Women constituted three out of five of this increase. The economy was expanding, although not enough; the number of jobs was growing; and women, particularly mothers who aspired to higher living standards for their families, entered the job market in rapidly rising numbers.

* Economic consultant, former director, Women's Bureau, U.S. Department of Labor.

Prior to World War II, the majority of young women, on leaving school and college, sought jobs. In 1940, women's peak labor force participation rate of 48 percent was reached between the ages of 20 and 24. From the age of 25 onward, the likelihood of women working diminished rapidly, and by the age of 45–54, less than one quarter of those in the age group were wage and salary earners.

Today, the peak labor force participation rate is still reached by those 20–24 years old; 65 percent of women of this age are workers. But the most significant contrast with the prewar period is, that after their mid-twenties, far fewer women drop out of the labor force and, when they do, their absence is much shorter. The civilian labor force participation rate is presently 57 percent for women aged 25–34 as well as for those aged 35–44, and it drops off only one percentage point for those aged 45–54. At age 55–64, 2 out of 5 women are still wage earners, a proportion only a little lower than it was 25 years ago among those most likely to seek employment—the 18–24 year olds.

The increase in the labor force participation rate of mothers of children under 18 has been exceedingly rapid; it quintupled between 1940 and 1974. The availability of jobs, the reduction in family size, and the rising cost of child rearing were major contributing factors.

Women, especially mothers, work for

the same reasons as men. They need the money. Nearly three quarters of all working women are single, widowed, separated or divorced, or have husbands with incomes of under $10,000. Employment is a compelling economic necessity for the 2½ million working mothers of children under 18 who head their own families. The earnings of more than half of the 11 million employed mothers living with their husbands, and who have children under 18, take their families out of poverty or help assure them of a minimum adequate standard of living.

As of March 1975, 55 percent of mothers with children aged 6–17 only, were wage and salary earners—a participation rate that had nearly doubled since 1948. During this period, the rate for mothers with children under the age of six tripled, rising from 13 percent 27 years ago to 39 percent last year.

This development has created an urgent need for action. More than 6½ million children under the age of six have mothers who are gainfully employed. As a nation we have done very little to assure the provision of adequate care for them while their mothers must be away from home. This has become a national responsibility because only a relatively small proportion of families in which mothers of preschool children work can afford the cost of developmental child care. In consequence, a very large proportion of their youngsters are in essentially custodial care, some of it so poor as to be actually injurious. Our record, as a country, with respect to meeting day care needs, is shockingly inadequate compared with most other industrialized nations.

Licensed child care facilities have the capacity to care for only about one million children, and many of these homes and centers fail to meet generally agreed upon minimum standards. Our fish and wildlife departments can tell you the number of fish by species in all our major lakes, but we have no up-to-date official statistics on where most children are or how they are cared for—the last federal study of child care arrangements having related to 1965. Based on that study, undertaken jointly by the Women's and Children's Bureaus, we can estimate that about one-third are cared for in other people's homes and about 10 percent are in group centers. Perhaps as many as one-half the preschool children of working mothers are cared for in their own homes, although few working parents can make satisfactory in-home care arrangements, at a price they can afford. In many homes, fathers who work at night and try to sleep during the day, watch out as best they can for their youngsters—hardly developmental attention. Many studies have revealed that large numbers of school-age children are kept home from school to look after younger siblings. An estimated 10 percent go with their mothers to their places of work. The number of latch-key tiny tots on their own is acutely disturbing.

No less distressing is the almost total lack of before and after school care for young school-age children whose mothers work. What is more, the gap between the supply of adequate child care services and the need for them is widening.

Under the able leadership of Senator Walter F. Mondale, constructive legislation was introduced and was passed by both Houses of Congress only to be vetoed by President Nixon in December 1971. A more modest bill is now pending but its prospects have been diminished by the well-financed opposition of a few, small groups one of which was largely responsible for the language of the Nixon veto. Another is disturbing flyers widely, falsely claiming that the bill would take

children from their parents, make them wards of the State and give them the right to sue their parents.

The plight of children and the anguish of working parents who can't afford to purchase good care can no longer be ignored. And working parents are not the only ones who want and need the expansion of good facilities which requires public support. Part day services should be available especially for children in economically disadvantaged families in which the mothers are not gainfully employed but who want their children to have development opportunities beyond those available at home. Only a few hundred thousand are now in programs such as Head Start. There are very few facilities for the children of students or of nonemployed mothers who, because of health or other problems, cannot care adequately for their children during the day.

## I. Women's Occupational Status

Another urgent problem with respect to women's economic status is the serious underutilization of their skills and talents. We are moving far too slowly to redress it.

Employed women today are heavily concentrated in the lower paid, lesser-skilled occupations which they have traditionally held. In 1973, more than a third of them held clerical jobs and more than a fifth were in service trades with average annual earnings in these two areas, for year-round, full-time work, of about $6,500 and $4,100, respectively. More than an additional fifth were sales, craft and kindred workers, and operatives, with mean average earnings in these three fields combined of less than $5,000 (year-round, full-time).

Fifteen percent of working women are in the professional and technical category, but nearly half of them are concentrated in three traditionally female, and relatively low paid, occupations: elementary and preschool teachers, registered nurses and health technologists.

Women's employment pattern remains very different from that of men. They comprise 40 percent of the total labor force but they are 98 percent of all registered nurses, and also of household workers, 85 percent of all elementary school teachers, 77 percent of those in clerical occupations, and 58 percent of nonhousehold related service employees. And three quarters of all working women are in these five fields, characterized by low average earnings.

As was earlier stated, 60 percent of the increase since 1950 in the total number of workers has been comprised of women. That they have moved even more concentratedly into the relatively disadvantaged jobs is indicated by the fact that their median wage and salary income for year-round, full-time work fell from 64 percent that of men in 1955 to 57 percent in 1974. And the gap has widened in every major occupational group with the one exception of service jobs, excluding private household employment.

In 1973, the median wage and salary income for year-round, full-time work was $6,448 for women and for men—$11,306. Nearly a third of these women earned less than $5,000, as compared with fewer than 1 out of 10 men. At the other end of the income range, only 2 percent of the women earned $15,000 to $25,000; the percentage for men was nearly ten times higher. And at the top of the ladder, less than one third of one percent of the women earned salaries exceeding $25,000; the proportion of men who did so was more than 18 times higher.

Some contend that encouraging employment trends are in process for women because the fastest increase in their

employment in any of the 9 major occupational groups, during the past 20 years, has been in the professional and technical occupations. It is true that women's numbers have more than doubled in these fields during this period, but the number of men in them has increased almost as rapidly. Women represented 38 percent of those in these relatively advantaged occupations in 1955; the proportion subsequently increased by only 3 percentage points—to 41 percent in 1973, but it is still some distance from the 1945 ratio of 47 percent.

It should be noted that in recent years women have become even more crowded in the lower ranks of the professions. In 1961, the median earnings of year-round, full-time professional and technical women workers were 68 percent those of men in such employment. In 1973, the ratio, a measure of relative occupational position, was down to 64 percent.

At the more privileged end of the professional ladder, women remain poorly represented. In 1974, women were 7 percent of all lawyers and judges, 10 percent of physicians, 14 percent of all chemists, 20 percent of computer specialists and 31 percent of all college and university teachers, to mention a few examples.

Even within these underrepresented professions women concentrate at the lower end of the scale and some trends are actually regressive. For instance, in our colleges and universities in 1974; women were 9 percent of all full professors—down from 10 percent in 1959–60; they were 15 percent of associate professors—down from 17.5 percent in 1959–60; and they were 24 percent of assistant professors and 45 percent of all instructors. These last two ratios were higher than in the base year but these gains did not compensate for the declines at the higher levels, so that, overall, women lost salary ground relative to men. At each of the teaching levels the average compensation of women was lower than that of men—the difference for all ranks combined averaging 18 percent.

Another illustration is employment in the Federal Civil Service. While Uncle Sam might well be expected to be the pacesetter with respect to affirmative action policy, being charged by an Executive Order to prohibit discrimination on the basis of sex in federal employment, an analysis of Federal Civil Service reports indicates that the mandate is far from fulfilled. Women in 1973 were only 34 percent of total white-collar federal employees—the same proportion as in 1968, and one much lower than their proportion in the total labor force. Not only had their number in the Service failed to keep pace with their growing role in the general economy, such progress as they have made at the top, in recent years, has been very slight.

In 1973, women were only 2.4 percent of all those in the three highest grades—GS 16, 17 and 18—up from 1.5 percent in 1968. They were 4 percent in the next two highest grades—GS 14 and 15—up from 3.4 percent in 1968; and they were 7.5 percent of those in the middle ranks, GS 12 and 13—up from 5.7 percent five years earlier.

That competent women are available to fill higher jobs needs no argument. Suffice it to say that in the government of the District of Columbia, which I serve as Chairperson of its Commission on the Status of Women, women comprise 10 percent of those in grades 16–18, 15 percent in grades 14 and 15, and 25 percent in grades 12 and 13 (all at the same pay scale as in the Federal Service). This is a record, I might add, many times better than that of the federal government, but it is one with which my Commission is rightfully far from satisfied.

Clearly, discriminatory hiring and pro-

motion practices seriously impede women's employment progress, despite the very encouraging legislative gains achieved since 1963. One of the many challenges is the need for far more effective enforcement of the Equal Pay Act, of Title VII of the Civil Rights Act, of State Fair Employment Practices and Equal Pay Laws, of Executive Order 11246 (as amended by Executive Order 11375) which prohibits discrimination on the basis of sex by federal contractors and subcontractors, and on federally assisted construction projects, of Executive Order 11478 which prohibits discrimination in Federal employment, and of Title IX of the Education Amendments of 1972 which prohibits sex discrimination in federally funded education programs and activities. Enforcement must also be better financed. The backlog of cases is of serious magnitude. More women need to bring their complaints to the agencies as individuals and as groups, and brings suits into court.

Educational efforts are vital to change employer attitudes as well as practices. Parents, teachers and vocational guidance personnel need to be far more aware of their responsibilities to help young women anticipate the realities of their work futures, to set their sights higher, and to prepare to use their abilities to the full. Too many of our girls are steered into traditional deadend jobs. Training programs must be desegregated and greatly improved. Blatant sexism in teaching materials in current use in many schools must be eliminated.

This is not to say "all women should work." Freedom of choice remains basic, to the extent economic considerations make it possible. But the reality is that the majority of women are now jobholders and their proportion will continue to increase. It is a terrible waste for them and for society that brains, skills and energies that have no gender, should be as conspicuously underutilized as they are today.

It is sometimes suggested that because of women's family as well as job responsibilities, greater discontinuity in their employment is inescapable and that this will continue to make for job status sex differentials. But intermittency in women's employment has greatly diminished and its extent is frequently exaggerated. Men are assuming more responsibilities in the home. This trend will accelerate. Few adequate studies have been made, but such data as are available indicate that the gap between the quit rates of men and women, when properly compared, is not wide and has been narrowing. Interestingly, in occupations in which there are large numbers of both men and women, recent studies indicate that occupational mobility rates were higher for men than women.

There are no differences in the overall levels of educational achievement of men and women sufficient to account for the great differences in their employment patterns. There is virtually no gap in the mean number of years of schooling completed—12.1 years by women workers and 12.0 by men. In 1974, a higher percentage of women workers than men had completed high school but a slightly smaller percentage had had some college education—28 as compared with 31 percent. In the area of higher professional occupations where advanced degrees relate to career achievement, it should be noted that women received 43 percent of all masters degrees last year—a somewhat higher proportion than they represented in the labor force, and an all-time peak.

Differences with respect to the percentage of doctoral and first professional degrees received by women do play an important role in upward mobility at some of the highest job levels. In 1974, women received 19.1 percent of all Ph.D.s.

Might I add that in economics, women are not doing as well as we should. In 1974 we received only 9.5 percent of the doctorates granted, but perhaps there is some comfort that this is about double the 1960 proportion.

With respect to first professional degrees there have been some dramatic breakthroughs that bode well for the future relative job status of women in the professions.

During the period 1969–74, the percentage of women among first year enrollees in the medical schools rose from 9 to 22 percent, and in law from 6 to 23 percent. By 1974, women were 31 percent of first-year students in pharmacy and 25 percent in veterinary medicine. There are lags, however, in other professional fields. Women are still only 6 percent of students enrolled in schools of engineering, 7 percent in dentistry, 9 percent in architecture and 10 percent in optometry.

While we are mentioning breakthroughs, a few interesting developments in nonprofessional fields might be referred to. Between 1960 and 1970, the number of women working as craft and kindred workers increased from 277,000 to 495,000—a rate of increase 8 times that for men in these skilled trades. They include carpentry, for instance, in which the number of women rose from 3,300 to 11,000; women electricians increased from 2,500 to 8,700; plumbers from 1,000 to 4,000; auto mechanics from 2,300 to 11,000; and tool and die makers from 1,100 to 4,200. But lest too many rise up to cheer, let me caution that women remained only 1 to 2 percent of all those employed in these five trades.

There is another heartening note. While, as I stated previously, the earnings gap between men and women has been widening, the gap between the earnings of black and white workers have become considerably smaller over recent years.

In 1939, the median year-round, full-time earnings of nonwhite women was 38 percent those of white women. By 1973, the ratio had risen very sharply to 88 percent, reflecting diminishing racial differences in the occupational patterns of the two groups. Measured in constant dollars, the earnings of nonwhite women, for year-round, full-time work, increased 5½ fold from 1939 to 1973. They needed to; they were so tragically far behind. Minority men's earnings, which have been 45 percent those of white men, rose by 1973 to 72 percent.

## II. Unemployment is Higher for Women than Men

Generally, the lower the status of the job, the more subject it is to unemployment. This is one of the main factors accounting for the greater vulnerability of women to unemployment, which averaged 30 percent higher for them than men during the past 25 years. Another element is seniority practices leading to the first firing of the last hired, which affect women disproportionately, especially minority women. These rules should be adjusted when they perpetuate past discrimination or impede affirmative action goals.

Officially recorded unemployment among women reached a post-World War II peak at the high rate of 10.2 percent in May 1975. As of October, the rate was still 9.1 percent. (Both May and October rates are seasonally adjusted.) The comparable rates for men were 8.5 and 8.2 percent, respectively. Unemployment among women during the first 10 months of 1975, averaged 57 percent higher than in 1973.

## III. Some of the Special Economic Problems of Minority Women

Before coming to a close, I want to add a few additional comments about the relative economic status of white and minority

women. Of all women in the labor force in 1974, 32.9 million were white and 4.9 milion, or 13 percent, were members of minority races (of which about 90 percent were black).

For many years the labor force participation rate had been higher for minority than white women. In 1947, it was 47 percent higher. That year 46.9 percent of minority women were in the civilian labor force, as compared with 31.8 percent of white women. Subsequently, this difference markedly diminished. By 1974, the labor force participation rate of nonwhite women was 49.1 percent, but that of white women has risen far more rapidly and was 45.2 percent. The differences in these growth rates would, undoubtedly have been less had minority women not been far harder hit by unemployment.

Recorded unemployment among minority women was 78 percent higher than among white women during the period 1949–74, averaging 9.1 percent as compared with 5.1 percent. And, it should be stressed, official unemployment rates are more understated for minority women.

The larger financial responsibilities of minority women is another factor which might have lifted their employment rates faster, had more jobs been available. The average earnings of nonwhite males are lower than those of whites, as earlier discussed, which puts added pressure on minority wives to seek work. Further, a far larger and more rapidly growing proportion of minority women than white, head their families. In 1974, more than a third of all minority families were headed by women, as compared with one out of ten white families. (The respective proportions had been 24 and 9 percent in 1965.)

Despite these comparative difficulties, the occupational pattern of minority women has been improving relative to that of white women. In 1965, 55 percent of all employed minority women were in service occupations; this proportion had dropped sharply to 37 percent by October 1975. Today, a much larger proportion of women in the relatively more advantaged white-collar jobs are members of minority races—their proportion having risen from 25 to 43 percent during the past ten years.

But there are still marked occupational differences between the two groups of women. While 37 percent of minority women are in service occupations, this is nearly twice the proportion of white women in this occupational category. And while 43 percent of minority women are now in white-collar jobs, this compares with more than 65 percent of white women. These, among other differences indicate the continuing need for the intensive acceleration of efforts to eliminate racial disadvantages.

That occupational differences between the two groups of women may be expected to narrow to a greater degree in the years immediately ahead is indicated by the fact that the gap between the occupational status of white and minority women, aged 16–34, is very much narrower than between women 35 years of age and older. This reflects progress especially with respect to relative educational opportunities. There is now virtually no difference between the median years of school completed by white and minority women workers (12.5 and 12.3 years, respectively, in 1974). Only 15 years ago, there was a difference of 2.8 years. There is much still to be done, nonetheless to assure the equalization of education with respect to quality.

This brief comparison of white-nonwhite economic status cannot be concluded without some mention of the special unemployment problems of minority teenagers, both male and female. Their recorded unemployment rate is unconscionable. It was 32.9 percent last year

and to the outrageously high postwar peak of 41.6 percent in March 1975, when the rate was more than double that of white teenagers. During the past 25 years, to be teenaged, black and female has added to the unemployment hazard; their unemployment rate has averaged 25 percent higher than for nonwhite boys.

Including the estimated number no longer actively searching for jobs, and hence not counted as unemployed, nearly one out of two nonwhite teenage girls who want work are now jobless. This is a miserable way to enter adult life in this the richest country on earth, fully capable of providing jobs for all.

## IV. Additional Targets for Action

Every year from next year forward should be International Women's Year until today's glaring inequities are eliminated. I have already touched on some much needed targets for action—including the need for increases in services, more effective administration and enforcement of laws and orders prohibiting sex and racial discrimination, and educational and other efforts to change attitudes and practices which now perpetuate employment barriers. Let me mention just a few additional challenges.

There is urgent need for reform of our social security system to eliminate inequities. Women are more likely to collect higher benefits as their husbands' dependents than as workers in their own right.

Our unemployment insurance system also needs reform. In more than 30 states, women are disqualified from compensation because of pregnancy, regardless of their ability to work. Part-time workers are not covered by unemployment compensation—and 26 percent of all women work part time—a third of them year round. Some 10 million workers, mainly women are still excluded from state unemployment insurance programs.

Many inequities with respect to taxation should be eliminated. The cost to working women of child care services should be deductible as a business expense.

Minimum wage rates lag behind soaring living costs. They should be lifted to make life more liveable for many of our most deprived families, the majority of which are headed by women. And it is imperative that an income maintenance program that would assure all families at least an adequate minimum living standard, replace our welfare system.

The Equal Rights Amendment must be ratified.

Women in far larger numbers should run for political office at the national, state and local levels. There is a long way to go when so few are in Congress, and when only 8 percent of our state legislators and 4 percent of the mayors of our 1000 largest cities are women. Women must press for far more adequate representation on appointive boards and commissions.

And there is one central underlying goal on which virtually all others depend. We must recognize that a healthy economy, growing at the rate it is capable of, is essential if there are to be jobs enough, opportunities for economic advance, and economic justice for all our people. The price we pay for the waste of our human resources when economic stagnation and recessions recur, is incalculable.

All these goals call for more than words. They call for mobilization for action for which economists have a very special responsibility.

1976 is Bicentennial Year. If we accept our responsibility, let us hope it will not be long before we shall be able to say that the Declaration of Independence has at long last been extended to all our citizens—holding the truth to be self evident that all men—and all women—are created equal.

# The Economic Position of Women in the United Kingdom

*By* NANCY SEEAR*

For women, as for men, it is the ownership of wealth and the acquisition and maintenance of income which together determine their economic position. This paper attempts to establish, so far as available information permits, the nature of the existing economic situation of women in the United Kingdom at the present time, to explore the reasons for the position, and to examine, tentatively, factors which may lead to changes over the next decade.

Accurate estimates of the distribution of wealth are notoriously difficult to calculate, but according to the recently published report of the Royal Commission on the Distribution of Income and Wealth, in 1927 women in England and Wales owned 33.1 percent of total wealth, the figure rising to 42.2 percent in 1962 but falling again to 39.4 percent in 1973. In the year 1973 there were 20,400,000 males aged 15 and above and 22,800,000 females aged 15 and over in the United Kingdom (i.e., Great Britain and Northern Ireland). In the same year it was calculated by the Inland Revenue that total personal wealth in Great Britain amounted to £163,900 million, distributed among 19.1 million wealth holders. Of these wealth holders 11,009,000 were men and 8,131,000 were women, and of these 4,087,000 or approximately 63 percent of the men, as compared with 4,316,000 or 52 percent of the women, owned under £3,000, while 2,759,000 or 25 percent of the men but only 1,617,000 of the women owned £10,000 or over.

* London School of Economics.

From these figures it is apparent that for the great majority of women it is on income rather than on ownership of wealth that they must rely almost entirely to maintain their economic position. To a lesser extent this is also true of men. It is estimated that in 1973 the bottom 80 percent of the total population, male and female, aged 18 and over, owned 13.6 percent of the total personal wealth in the country.

These figures must be interpreted cautiously. Different methods of calculation and the exclusion of certain categories of wealth from the Inland Revenue statistics on which they are based can lead to considerable variations in the estimates. But however calculated, it is clear that the ownership of wealth is of marginal importance except for the few. In assessing these figures it must on the other hand be borne in mind that 52 percent of all householders owned or were purchasing their own house in 1973. This is of particular value to married women, whether or not the house is in joint ownership. Women's expectation of life is longer than that of men. There are more than double the number of women than men over the age of 80. An increasing number of married women can therefore look forward to the ownership of their own home during their period of widowhood.

Clearly for the great majority of women it is the ability to earn a salary or wage and to establish rights under public or private social security schemes which is of the greatest importance. How do women fare in these respects?

TABLE 1—GREAT BRITAIN

| | Median Earnings | Lowest Decile | Lower Quartile | Median | Upper Quartile | Highest Decile |
|---|---|---|---|---|---|---|
| | £ per annum | % | % | % | % | % |
| Men | | | | | | |
| 1964/65 | 934 | 65.2 | 80.8 | 100.0 | 123.6 | 155.9 |

*Source:* Royal Commission on the Distribution of Income and Wealth, report no. 1. Derived from DHSS Statistics of Earnings.

Table 1 shows the distribution of earnings for both men and women in the years 1964–73. They cover the annual earnings of men and women aged 18 or over in full- or part-time employment throughout the year, median earnings, and deciles and quartiles as percentages of the median for 1964–65 to 1972–73. Median earnings distinguishing between manual and nonmanual workers, and between men and women for the years 1970–74 are given in Table 2.

These figures are not strictly comparable with the figures in Table 1 as they are based on the gross weekly earnings of full-time males aged 21 and over and full-time female employees aged 18 and over, whose pay for the survey period was not affected by absence.

In comparing these earnings figures, it has to be remembered that earnings are increased by overtime and shift working which is undertaken by men to a much greater extent than by women. In 1971,

TABLE 2—MEDIAN EARNINGS
(£ per week)

| | Manual Men | Nonmanual Men | All Men | Manual Women | Nonmanual Women | All Women |
|---|---|---|---|---|---|---|
| 1970 | 25.6 | 31.4 | 27.2 | 12.8 | 15.9 | 14.6 |
| 1971 | 28.1 | 34.4 | 29.8 | 14.6 | 18.0 | 16.6 |
| 1972 | 31.3 | 38.5 | 33.4 | 16.4 | 20.1 | 18.6 |
| 1973 | 36.6 | 42.8 | 38.4 | 18.9 | 22.3 | 20.9 |
| 1974 | 41.8 | 48.5 | 43.8 | 22.7 | 26.1 | 24.7 |

*Source:* Royal Commission on the Distribution of Income and Wealth, report no. 1. Derived from NES, 1974, Table 15.

for example, so called normal working hours for manual workers were 40 for both men and women. But in the industries and sources covered by the regular earnings enquiries, which include all manufacturing industries, men averaged 44.7 hours and women 37.7. If women officially classified as part-time workers, i.e., working 30 hours or less are included, as they are in Table 1, the actual average working hours for women dropped to 32.4.

In 1971, only 3.9 percent of all male workers, but 33.7 percent of all female workers, worked 30 hours a week or less, while 47.8 percent of men but only 12.6 percent of women worked over 40 hours. Even if women officially classified as part-time workers are excluded, as in Table 2, only 22.4 percent of women manual workers worked 40 hours or more compared with 64.5 percent of male manual workers. The contrast among nonmanual workers is far less sharp. Among nonmanual full-time workers, men averaged only 1.7 hours more than women and about 40 percent of both sexes worked 36–38 hours. Even among nonmanual full-time workers however, 30.9 percent of women but only 19.2 percent of men worked 36 hours or less, while 8.6 percent of men but only 1.6 percent of women worked 45 hours or more.

With these reservations, the Department of Employment, in summarizing trends was able to comment:

> In recent years average weekly and hourly earnings of women have increased relatively faster than those of men, both among non-manual and among manual employees . . . The New Earnings Survey shows, for example, that between April '72 and April '73 the percentage increases in average weekly earnings, excluding overtime earnings for full-time manual workers were 16.2% for women aged 18 and over but 15.1% for men aged 21 and over; and for full-time non-manual workers they were 13.7% for women but 12.8% for men. [p. 30]

Women's economic position, insofar as it depends on earnings is therefore relatively, if slowly improving. But with a median earnings figure of £24.7 in 1974 it can hardly be regarded as strong.

If women's income is not high, can it be considered secure? Security depends mainly on two factors: on the relative reliability of employment, and on the provision available to plug the gap when earnings are interrupted or cease.

In the United Kingdom in recent months, unemployment figures have been rising to a level not experienced since World War II. Contrary, however, to the expectations of some commentators the employment of women does not appear to be affected worse than that of men. This is perhaps not surprising since women are to so large an extent confined to customary women's jobs. They are therefore complementary to and not in competition with men in the labour market. If and when the aims of the Sex Discrimination Act are achieved, and jobs are open indiscriminately to men and to women, the protection afforded by the present organization of the labour market may well disappear, and women may in practice be more vulnerable, despite the safeguards in the Equal Pay Act and in the Sex Discrimination Act.

Though women are not more likely to experience unemployment than men, their position is much less favourable when, for any reason, earnings disappear. This is in part due to a curious provision in British Social Security legislation which has permitted married women employees to contract out of payment of Social Security contributions, except in relation to industrial injuries. In 1971, 61 percent of all women employees were married and about 75 percent of all married women employees took advantage of this right to exemption. A very high percentage of women employees are therefore not eligible for

unemployment benefit, for sickness benefit or for a retirement pension in their own right. This option has been removed in the Social Security (Pension) Act 1975, but not for married women already in employment.

As a result the great majority of married women are dependent, not only in sickness and unemployment, but also in old age on benefits earned by virtue of their husbands' contributions. These contributions provide the husband with a dependent's allowance for his wife, at a level considerably less than the pension the wife could have obtained had she taken up the option to be insured in her own right. She is also entitled to a widow's pension on the strength of her husband's contribution. If however, she is divorced and the husband remarries, it is the current wife, not the original wife, who qualifies for the widow's pension, though the first wife can make use of his contributions up to the time of the divorce to satisfy the contribution requirements for her own pension. This unsatisfactory situation underlines the importance of introducing social security policies which establish women's social security rights on an individual basis, regardless of marital status. The maintenance of income when earnings are interrupted does not of course depend entirely on payments from the National Insurance or Social Security funds. Increasing fringe benefits including especially company sick-pay schemes and occupational pension schemes are contributing an increasing proportion of income. How then do women fare in these nonstatutory schemes?

The Equal Pay Act 1970 required that there should be no discrimination by employers on grounds of sex in relation to fringe benefits such as sick pay and holiday entitlement, but explicitly excluded pensions and superannuation rights, the area which is of far the greatest importance. Under the Social Security (Pensions) Act of 1975, it is a condition of approval of a company superannuation scheme by the statutory Occupational Pensions Board, that there should be no

TABLE 3—PERCENTAGE OF FEMALE WORKERS IN MAJOR OCCUPATIONAL GROUPS, 1911–66

discrimination on grounds of sex in such schemes and this is reflected in the state superannuation provisions. This will ultimately ensure income-related superannuation payments to all persons, male and female, who have been in paid employment. The position of widows is also to some extent safeguarded by the requirements of the Occupational Pensions Board.

Since earnings and the fringe benefits dependent on earnings are decisive, the opportunities available to women in the labour market are crucial. In the United Kingdom, as to a greater or lesser degree in all western democracies, there are virtually two labour markets, a men's labour market and a women's labour market. The distribution of jobs has been dominated by the assumption that there are men's jobs and women's jobs with little if any scope for interchangeability. There are two major characteristics of the women's labour market: women are concentrated in a small number of occupations and are to be found to a marked degree in the lower levels of employment.

> Analysis by occupational order of the 8,344,100 female employees in employment showed that 2,429,800 (or 29.1%) of all female employees were 'clerical workers'; 1,931,700 or 23.2% were service, sports and recreation workers (e.g. canteen assistants, cooks, office cleaners); 994,600 (11.9%) were professional, technical workers and artists (e.g. teachers, nurses); and 896,400 (10.7%) were 'sales workers.' These low occupational orders in total accounted for nearly three quarters of all female employees.[1]

Table 3 shows the underrepresentation of women in the more responsible, interesting and skilled jobs, while Table 4, giving the number of girls entering the apprenticeships to skilled occupations in Great Britain in 1972 makes it clear that no great change can be expected in the near future in view of the small number of girls entering training for skilled work on leaving school.

TABLE 4—GIRLS AGED 15–17 ENTERING APPRENTICESHIPS TO SKILLED OCCUPATIONS IN 1972—GREAT BRITAIN

Table 5 demonstrates how far women lag behind in the professional field.

This is a familiar picture. The reasons for it are in the main similar on both sides of the Atlantic. Deep rooted cultural assumptions are no doubt at the heart of the matter, assumptions which are reflected in influences in the home, in the behaviour encouraged in girls in contrast to boys, in educational provision and in employers' and trade unionists attitudes. These attitudes are so deep seated that they are frequently totally unrecognized: unlike racial prejudices, their recognition, when it occurs, is rarely accompanied by any feeling of guilt. It is also true that such traditional attitudes are often found in women as well as in men. In a study which I carried out in 1962, women in positions of responsibility were asked about their attitude toward women bosses. Those who had never experienced a woman boss overwhelmingly held the traditional view that a male boss was to be preferred. Inter-

[1] This extract is based on the 1 percent sample results of the 1971 Census of Population.

[a] The figures were provided at various dates between April 1971 and September 1972. Membership categories vary but are the same for both men and women in each association's estimates.

[b] There were 7 women members.

[c] About 5 noncorporate members were women.

estingly, among those women who had actual experience of a woman boss, the predominant attitude changed, not to a preference for a woman, but to indifference to the sex of the boss. At the present time when additional resources are being made available under the British Manpower Services Commission for the retraining of women returning to the labour market, a very high percentage of women taking advantage of the new grants are choosing to train for traditional women's jobs.

Attitudes are of prime importance. But at a different level, lack of knowledge also contributes substantially to the present position. In particular many people, especially many employers, do not appear to appreciate the significance of the important demographic changes of recent decades. At the turn of the century when the vast majority of women worked for a very few years between school and marriage and did not contemplate returning to paid employment, there was a rational case against the investment of time and money in training girls. Today, with a falling birth rate and childbearing normally completed before the age of thirty, that argument has lost a great deal of its force. Because employers have not grasped the full implications of this demographic and social revolution, they have not analyzed the ways in which the new type of female labour force can best be deployed; nor have they realized the economic benefits that can be reaped from the new situation. For example, throughout most of the 1950's and 1960's employers suffered from an acute shortage of draughtsmen. Scarcity pushed up draughtsmen's rates, and perhaps even more damaging from the employer's point of view, the inability to get designs off the drawing board delayed production and postponed delivery dates. During this time women in Sweden were being trained as draughtsmen in such numbers that by the end of the 1960's more than half the Swedish draughtsmen were in fact women. In the United Kingdom on the other hand, only 1 percent of the total number of draughtsmen were women by that date.

In much the same way the full significance of the greatly increased tendency for women to return to work after a short period at home for childbearing has not been appreciated. Women reentering the labour market in their middle thirties have a quarter of a century of working life ahead of them. The investment of time and money in training can clearly be justified in terms of a reasonable likely return. Extensive training will not be

appropriate for, or wanted by, all women. Careful selection for women suitable for such training is needed as it is for men. But there has been little attempt to tackle the task of making better use of this newly available womanpower, except in a piecemeal manner.

Many women, as is often pointed out, want only part-time work. But even these cases, handled with discrimination, can be used far more advantageously than at present. Despite increasing efforts to improve job satisfaction, repetitive or limited jobs remain. Such work is more acceptable on a part-time than on a full-time basis. It is also wasteful both from the employer's and the women's point of view to restrict part-time employment to work of this nature. Though it can be argued convincingly that there are jobs, particularly executive positions in line management which require full-time attendance, there are many others, for example in research and in many types of professional and office work, which in reality need not be full-time. Employers stand to gain from such changes, as able people at present underutilized or not employed at all, can be drawn into employment on these terms. A growing number of employers may also find, as employers in retail distribution found years ago, that there are many situations in which work-loading is such that it is far more economical to employ staff part-time rather than full-time.

What is required is in fact a straightforward management job of assessing requirements and resources and finding ways of making the most effective use of the new supply of womanpower. This, as so often, demands a surrender of preconceived ideas, and the use of the right kind of discrimination. In particular, it requires the abandonment of familiar stereotypes. The advancement of women has suffered severely from generalizations about women's labour turnover rates, women's absence rates, women's attitudes to work, regardless of the long list of other important variables which must be taken into account in attempting to predict the behaviour of either men or women. Once this is done, there is plainly a pay-off both for employers and for the community as a whole. The United Kingdom is in no position to waste its resources, most especially its human resources and the underutilization of British womanpower is a glaring example of such waste.

What then is being done, and what results may be expected from these changes?

Three Acts of Parliament have been passed which provide the foundation for much needed change. The Equal Pay Act 1970 set out "to prevent discrimination, as regards terms and conditions of employment between men and women." A three-pronged attack on unequal pay is made in the Act. If a collective agreement contains a discriminatory clause, the agreement can be altered by the Central Arbitration Committee. If job evaluation exists in an enterprise, it must be applied uniformly to men's jobs and to women's jobs. If there is no scheme of job evaluation, a woman can claim the same pay as a man if, but only if, "her work and theirs is of the same or a broadly similar nature." Whether or not work is of a "broadly similar" depends on the nature, the extent and the frequency of the differences.

This Act, though passed in 1970, only came fully into force on December 29, 1975. As soon as it was passed, men and women concerned with the position of women in the economy began to campaign for equal opportunity legislation to complement the Equal Pay Act. Without such additional legislation it seemed likely that equal pay legislation, welcome though it was in many ways, might in fact adversely affect the position of a considerable

number of women. The merging of the men's labour market and the women's labour market would become a necessity if women, displaced from women's jobs by the operation of equal pay legislation, were to obtain appropriate and satisfactory new openings. The need for this change was underlined by manpower forecasts such as that produced by Colin Leicester then of the Department of Applied Economics at Cambridge. Leicester estimated that between the years of 1960 and 2000 the percentage of the working population in clerical and manual work would fall from 12 percent and 70 percent, respectively to 9 percent and 61 percent while the percentage in professional and technical work would rise from 8 percent to 20 percent. Since women were overrepresented in clerical and lower level manual work, and underrepresented in technical work, it was essential to challenge the sex categorization of these jobs if women no longer needed in the clerical and manual fields were to become available for the growing range of technical jobs.

The campaign for equal opportunity culminated in the Sex Discrimination Act 1975 which also comes into force on December 29, 1975. This Act prohibits discrimination on grounds of sex or marriage in many cases including education, training or employment, with a small number of exceptions based mainly on a fairly tight interpretation of genuine occupational qualifications. An important subsection lays down that if the employer applies a condition or requirement which is such that a considerably smaller proportion of men than of women can comply with it, the condition can be challenged, and the employer has to show that it is "justifiable." This section could be very important and very explosive. What about time-served apprenticeship requirements? What about seniority rules?

These two Acts have been supplemented by the Employment Protection Act 1975, which includes a section on maternity benefit. For the first time in the United Kingdom a woman who fulfills the necessary conditions of service cannot be dismissed for pregnancy, can claim six weeks pay as pregnancy leave and has reinstatement rights for a period of twenty-nine weeks. Although child care provisions are quite insufficient to enable a large number of mothers to take advantage of these new rights, it will make it easier for some at any rate to combine a career and motherhood.

Such is the legislation. How much difference will it make to the position of women, and what changes can be expected in women's economic position, in particular in the employment field?

So far as individuals are concerned, the enforcement of equal pay and equal opportunity legislation is mainly in the hands of Industrial Tribunals, which already deal with such matters as claims under the Redundancy Payments Act, and with which people in employment and their union representatives are very familiar. In addition, an Equal Opportunities Commission has been set up with a broad mandate to work towards the elimination of discrimination, to promote equality of opportunity and to keep the working of the legislation under review. The Commission has powers within certain limits to carry out formal investigations and, where they find discrimination, to serve a nondiscrimination notice to be followed up by investigation to establish whether the requirements of the notice are being carried out. If the Commission is not satisfied, the case can be referred to a county court which may grant an injunction. The Commission can also undertake research and educational work and is already taking steps to see that rights and obligations under the Acts are widely known. The legislation does not

give the Commission or anyone else power to require positive discrimination in favor of women except in the very important field of training.

To an American audience it may seem that these powers are inadequate. There are however reasons why, at any rate in the British context, it seems right to place the emphasis on education, training and persuasion and while providing legal sanctions to keep these sanctions in the background. The existence of the law puts the seal of society's approval on the elimination of sex discrimination. It also undoubtedly draws the attention of educationalists, employers and trade unions to the need to examine their existing practices and to begin a process of change. While this is not yet widespread, there are certainly signs that it is beginning to happen. Above all, as has often been said, legislation can help to change attitudes by changing behaviour, but it is the change in attitudes that is important. In other fields of social policy, it is accepted that individuals do not change attitudes as the result of authoritarian action taken by powerful individuals or organizations. Such action more often breeds evasion or at most a minimum conformity with the law, accompanied by a growing resentment which blocks genuine change. It may be slower to help and encourage those who have to change to work out their own methods and to take upon themselves the task of studying what needs to be done and learning, through experience, the way to do it. It may be slower, but there is always the fable of the tortoise and the hare.

Where women will be in ten years time is hard to predict. It depends in part on the future of the British economy, though it is possible that women, uncommitted to traditional working methods might have a specially useful contribution to make to industrial redevelopment. It depends on the realization by employees and unionists that the removal of discrimination though undoubtedly altering long established customs, can if handled right bring considerable benefits and not only to women. Above all, it depends on women themselves. The first stage must be a great increase in training opportunities. It will be for women to make sure that these opportunities are taken.

# Three Years of Self-Paced Teaching in Introductory Economics at Harvard

*By* ELIZABETH ALLISON*

For the past three years Harvard has been experimenting with self-paced instruction (*SPI*) in several sections of its introductory economics course, Economics 10. This paper is a report of the "what, how and for whom" of that experiment: what the benefits (and costs) of *SPI* have been, how *SPI* changes the learning process, and for whom among our students it has been particularly helpful.

The reader will note the lack of the evangelicalism often found in descriptions of educational innovations. This is not intended to suggest that self-paced instruction is without merit; indeed our evidence suggests quite strongly that under the right circumstances, the marginal product of *SPI* is a 10–20 percent increase in scores and that it inspires students to take more courses in economics. However, it is also true that producing the "right circumstances" is initially rather costly in time and energy; that the distribution of the benefits is not uniform; and that after an initial period of enthusiasm, students are not happier in self-paced courses than in conventional courses. In short situations in which an *SPI* system would not dominate a conventional course are plausible.

* Dept. of Economics, Harvard University. For a more extensive description of the self-paced experiment at Harvard, see "Self-Paced Instruction in the Introductory Economics Course," Elisabeth Allison, Harvard Institute of Economic Research, pap. no. 368.

## I. Some Background on the Harvard Experiment

The Harvard experiment with *SPI* began in the fall of 1972. Like most educational experiments, its birth was something of an accident; it was born of dissatisfaction with the mastery students displayed at the end of our introductory economics course and the discovery of an enormously intuitively appealing new educational technique which had worked well in physics and psychology. Briefly, a self-paced course has two central features.

The first is a list of the course objectives, specified in operational terms (these objectives can be very detailed), and the second is a set of exams (often called "unit tests") which the student is invited to try whenever he believes he has mastered an objective. The exam is graded immediately and the student who does not pass the exam is encouraged to return and take another exam on the same material. Full credit is given for passing an exam regardless of the number of unsuccessful attempts and a student's grade is to some extent based on the number of exams passed. Thus it supplies a student with prompt nonthreatening feedback.

The distinguishing features of the self-paced course developed at Harvard were three. First, it seemed appropriate to ask our students to synthesize some of the material themselves; thus we had a com-

paratively few broad units (8 per semester) and fairly high-level objectives. Second, whereas in many self-paced systems, objectives and unit tests replace formal meetings, in Economics 10, sections continued to meet although attendance was voluntary. Third, only upperclassmen or graduate students were used as graders, rather than allowing students who had passed a unit test to serve as graders for that unit test.

## II. A Framework for Evaluation

From its inception we had intended *SPI* as an experiment. Thus we had taken advantage of the decentralized structure of the course (it is taught primarily in sections, but has a course-wide reading list and final exam); *SPI* was introduced into 3 sections of 25–30 randomly selected students each semester over a three-year period. We had instituted, simultaneously, a very extensive, course-wide questionnaire and data gathering program, including admissions profiles and student effort reports.

Originally we had intended to follow the conventional evaluation format, of estimating an achievement equation in which a test score was the dependent variable and *SAT* scores, age, sex, and grade point average (*GPA*), the controls, perhaps improving upon it by collection of better ability measures.

However, the closer we looked the less satisfactory this format looked. Intellectually, the *ad hoc* specification of most achievement equations was unsatisfying. The lack of attention to the simultaneity problem seemed likely to produce serious bias in estimates of the coefficients. Moreover, it was not heuristic, as a good theory almost invariably is. Thus we gradually turned to an alternative framework: production theory. Deciding to evaluate *SPI* by treating it as a new technology in a production process brought several advantages. It opened up a well developed technology, both conceptual and econometric. It provided perspective on the limitations of the conventional approach; the economic education literature largely recapitulates the errors of early production theory. Finally, and most important, it made it clear that the development of a full scale model of the educational process was necessary for any thorough evaluation of an innovation. This is not to suggest that the development of an appropriate model within which to evaluate *SPI* has been accomplished. The lack of a generally accepted theory of learning and a severe errors-in-variables problem made the task of finding an appropriate structure and defining operational counterparts to the theoretical terms most difficult and our specifications are still tentative. Nevertheless, even the preliminary models have yielded some interesting results on *SPI* and on the learning process in general.

The simplest of these models, and the one within which our preliminary evaluation of *SPI* took place began as follows.[1] We assumed that the student (our decision-making unit) allocates his efforts among courses and other activities in such a way as to maximize some function:

$$U = f(Grades_{Ec\ 10}, Grades_{Other\ courses}, Time_{Ec\ 10}, Time_{Other\ courses}, Time_{Other\ activities})$$

This assumption allowed us to derive a 3-equation model which here, in the interests of space, we will merely state. The first line is an effort equation:

$$Effort^{i}_{Ec\ 10} = f(Tastes,\ Expected\ grade,\ Pedagogy).$$

Since this exposition is intended to be merely suggestive, we henceforth make the

[1] The construction and estimation of the Economics 10 production function are described in more detail in "An Educational Production Function for an Introductory Economics Course," Elisabeth Allison, Harvard Institute of Economic Research, pap. no. 563.

unnecessary but convenient assumptions of linearity and additivity and can therefore write the equation for the effort put out by the $i$th student as:

$$(1)\quad \mathit{Effort}^i = a + b_1^i\,\mathit{tastes} + b_2^i\,\mathit{expected\ grade} + b_3^i\,\mathit{teacher\ quality} + b_4^i\,\mathit{SPI}$$

The $i$th student chooses to devote some effort, $E^i$, to Economics 10. He faces a production function defined by his ability (presumed exogenous), pedagogy offered him by the course, defined by teacher quality and the instructional method, e.g., self-paced instruction. Thus we can write:

$$(2)\quad \mathit{Achievement}^i = a + b_1^i\,\mathit{effort} + b_2^i\,\mathit{teacher\ quality} + b_3^i\,\mathit{SPI} + b_4^i\,\mathit{general\ ability} + b_5^i\,\mathit{analytic\ ability}$$

In retrospect, enjoyment of a course depends on his "profit," i.e., the difference between the grade from the course and the costs of the course $E^i$ weighted by psychic or financial cost of that effort to him. What he received will depend on his grades and his tastes. Thus our third equation of our model of the learning process became:

TABLE 1—ACHIEVEMENT

| | (.61) | (2.67) | (4.72) |
| *SPI* | 3.8928 | 2.5161 | 3.0546 |
| | 4.45) | (2.83) | (2.54) |
| $R^2$ | .467 | .423 | .442 |

*Note:* The values in parentheses below the coefficients are $t$-ratios.

$$(3)\quad Enjoyment^i = a + b_1^i\, achievement + b_2^i\, effort + b_3^i\, tastes + b_4^i\, general\ happiness$$

Finally, believing that a continuing intellectual involvement with the discipline, as manifested by desire to take further economics courses is an important output of an introductory course for the student, we added a concentration equation:

$$(4)\quad Intended\ courses^i = a + b_1^i\, intended\ concentration + b_2^i\, intended\ career + b_4^i(Grade_{Ec\ 10} - grades\ in\ other\ courses) + b_5^i\, enjoyment + b_6^i\, SPI.$$

Thus, we had a model, admittedly crude and turning on heroic assumptions, which provided us with a framework and set of questions about *SPI* and the wherewithal to answer them; namely:

1. Does *SPI* have any net effect on learning, enjoyment or concentration? More precisely put, is $b^iSPI$ significant if all of the endogenous variables are suppressed?
2. How do these effects, to the extent that they exist, vary among students, i.e., does $b^iSPI$ differ systematically among definable classes of students?
3. If *SPI* has any effect on achievement, enjoyment or concentrations, what is the mechanism through which it works? Translated into the terms of our model the question becomes: Is $b^iSPI$ significant in the effort equation, but not in the achievement equation? Or vice-versa? Or in both?

## III. The Results

### A. The SP Effect

The answer to the first question is provided in Tables 1, 2 and 3. Table 1 shows the result of estimating equation 2 without the endogenous effort variable. Thus it provides an upper bound on the pure self-paced effect; Tables 2 and 3 show results for enjoyment and concentration equations, respectively. Given the space constraint and the similarity of results, only one semester's data is presented for the enjoyment and concentration equations.

Both the enjoyment and the concentration equations were somewhat disappointing. The *direct* contribution of *SPI* to student happiness is insignificant and its contribution to concentration decisions is small. In its initial year, 1972–73, *SPI* had produced both remarkably happy students and a very high proportion of concentrators. However, both the 1973–74

and 1974–75 results suggest very strongly that the 1972 experience was largely attributable to a Hawthorne effect of the very heavy faculty involvement in the grading process during the first year.

The achievement equation shows rather more encouraging results. On a multiple choice final made up of 10 *TUCE* questions, 20 *GRE* questions and 10 local questions with a 40 point maximum, and a mean score of 23, *SPI* does appear to improve performance by about 15 percent. Put differently, it substitutes for about 150 *SAT* points or 10 hours of weekly preparation by an instructor. Moreover, results available in the larger study mentioned earlier suggest that the differential increases after two years out of the course.

### *B. The Distribution of Benefits*

Having established that there were some identifiable education benefits associated with an *SPI* system it was appropriate to move to the second question: Who reaped those benefits? In particular, was the nonthreatening, repeat-play environment most helpful to the slower student and/or the bewildered humanities majors who did not yet understand how to study analytic material? Or was it an enrichment program which brought students into regular contact with very bright and stimulating upperclassmen and graduate students? To examine this question we stratified first by *SAT* scores (above 700/below 700), and then by year (freshman/nonfreshman).

Unfortunately the results were not as cleancut as we would have liked. (These regressions are available from the author on request.) In general, lower *SAT* groups and freshmen seem to be slightly more advantaged by *SPI* than higher *SAT* groups and upperclassmen. The differences between freshmen and upperclassmen are small and in any case not consistent over semesters. Thus it is clear we need to investigate the distribution effect with other group criteria. As an aside, the most interesting result of these regressions concerns the other instructional inputs: the marginal product of the well-prepared teacher is highest with the less brilliant student.

### *C. The SPI Technology*

Having established that a broad group of students did measurably better in a self-paced format, our next task was to find out why. The first hypothesis was that *SPI* had simply reinvented "study hall"; that *SPI* was primarily a device for getting students to work harder, or at least more steadily. To test this hypothesis we reestimated our achievement equation,

this time including the effort variables; homework hours, attendance, etc. The results for one semester, spring 1974–75, are shown in Table 4. Although the self-paced effect is slightly reduced it is not eliminated. This test is not conclusive. It is possible, for example, that *SPI* makes the study of economics so rewarding that hours seem like half-hours, and thus the reported work hours of the self-paced students are biased downward. Nevertheless, it appears *SPI* is not simply a system for sweating the students.

Given this finding we made one further test in an attempt to discover whether the defining of objectives, the self-knowledge, or the active interaction was the critical feature of SPI. For students in self-paced sections, we have two measures of participation: one, the number of self-paced exams each took and two, the number passed. (The number of *SPE*s attempted is generally larger both because many students failed a unit test on the first try, but also because after passing, some students would take additional tests "for practice.") Arguably, the number of *SPE*s passed measures self-knowledge, while number of *SPEs* attempted is a measure of the amount of interaction between student and grader. To discover which contributed more, we reestimated the achievement equation for the self-paced group only, using both *SPE*s attempted and *SPE*s passed as dependent variables.

TABLE 4—ACHIEVEMENT: FALL 1974
(Self-paced group only)

| | |
|---|---|
| *SAT* verbal | .0370 |
| (200–800) | (3.15) |
| *SAT* math | .0074 |
| (200–800) | (.75) |
| Class rank | −.0017 |
| (200–800) | (−.16) |
| Uncomfortable with math | .0221 |
| (1=yes, 0=no) | (.21) |
| Intrinsic interest | −.6103 |
| (1=much, 7=none) | (−1.48) |
| Sex | −.3958 |
| (1=female) | (−.29) |
| Race | 1.1903 |
| (1=minority) | (1.51) |
| Attendance | .4437 |
| (1=always, 7=never) | (.51) |
| Percent reading not done | −.6496 |
| | (−1.20) |
| Responded to questionnaire | −.6134 |
| (1=no/0=yes) | (.52) |
| Teaching fellow rating | −.5339 |
| (1=high, 7=low) | (−1.02) |
| *SPE*s passed | .5401 |
| | (3.51) |
| *SPE*s attempted | .2332 |
| | (2.14) |
| $R^2=.723$ | |

The rather remarkable results are shown in Table 4. "Self-paced exams attempted" captures a considerable amount of the variances, and even more interestingly, sharply reduces the coefficients on the ability variables. This result is consistent with the hypothesis that the crucial feature of *SPI* is the interaction between students and grader; that it is not just glorified homework but a very directed form of one-to-one instruction.

## IV. Some Tentative Conclusions

This study of *SPI* has no claims to be exhaustive: there are many other questions to be asked, and some better answers to be provided. Nevertheless, at least within the Harvard context it appears that we can purchase a fairly substantial and lasting improvement in scores for roughly $35 per student per semester. We seem to have allowed our students to substitute efficient, interactive hours for passive or unfocused hours although apparently not to their great pleasure.

Moreover, it is clear that moving to a *SPI* system brought about enormous improvements in our introductory course quite apart from its contribution to the learning of particular students. It forced us to reexamine our course objectives, to

# The Teacher Training Program for New Ph.D.s

*By* DARRELL R. LEWIS AND WILLIAM E. BECKER, JR.*

In 1970 the University of Minnesota Center for Economic Education initiated a teacher training program for graduate students in the Department of Economics. Prior to 1970, as is the case of most university departments of economics, new graduate students who were assigned to either the micro or macro principles course as section teachers were given a text, a sample syllabus, a class list, and a classroom number.[1] After five years of development and assistance from the Joint Council on Economic Education, graduate student instructors at Minnesota are now required to participate in a teacher training program. This paper is intended to provide an overview of the Minnesota program along with some preliminary evaluation results.[2]

## I. The Teacher Training Program

In their first quarter of teaching, graduate student instructors (*GSIs*) at Minnesota are expected to participate in nine weekly seminars dealing with teaching objectives, methods, and skills. They are also expected to participate in a three-part teaching performance feedback process which involves classroom videotaping, classroom test analysis, and student evaluations. In fact, participation in both the seminars and feedback procedures are now given as conditions of employment for all new graduate student instructors.[3]

### *A. The Seminars*

The seminar sequence of the program starts one week prior to the beginning of the fall quarter. The seminars are designed to acquaint the *GSIs* with the eleven teaching abilities identified in Table 1.[4] A senior faculty member together with an experienced senior graduate student takes responsibility for the content and manner in which the seminar is conducted. Participating *GSIs* are expected to complete basic exercises related to each of the eleven teaching abilities emphasized.

Seminar activities entail writing goals for the principles course, writing instructional objectives, discussing and demonstrating lecture skills, demonstrating alternative teaching techniques (large and small group), discussing and demonstrating the use of audiovisual materials, writing and grading examinations, evaluating student feedback, and developing student-

* Professor and Assistant Professor of Economic Education, respectively, University of Minnesota. We wish to recognize the significant contributions of Charles Orvis and Mike Salemi in the development and implementation of the programs described in this paper.

[1] On the basis of this observation the American Economic Association's Committee on Economic Education, in conjunction with the Joint Council on Economic Education, formulated its proposal to improve the teaching of college economics, G. L. Bach (1973).

[2] For a complete operational description of the University of Minnesota teacher training program in economics see Becker, *et al.* (1975).

[3] Since the pecuniary benefits to the graduate students are not weighted in favor of improving their teaching output, beginning in 1974 graduate students were required to participate in the teacher training program as a condition of employment, Becker (1975).

[4] Many of the instructional activities and pedagogical skills identified in Table 1 are discussed and developed in a forthcoming book edited by the Joint Council on Economic Education and entitled *Teacher Training Programs for Ph.D.'s in Economics*. This excellent source material is currently available for limited distribution in mimeograph form.

TABLE 1—TEACHING ABILITIES AND FEEDBACK

| Teaching Abilities Emphasized | Method of Feedback |
|---|---|
| 1. Recognize student needs | Student evaluations |
| 2. Set goals and write objectives | Daily teaching checklist |
| 3. Develop content sequencing | Student evaluation, videotaping, and teaching checklist |
| 4. Use lecture skills effectively | Student evaluations and videotaping |
| 5. Implement discussion skills effectively | Student evaluations and videotaping |
| 6. Demonstrate interpersonal communication skills | Student evaluations and videotaping |
| 7. Implement probing or questioning skills effectively | Student evaluations and videotaping |
| 8. Utilize multimedia materials effectively | Student evaluations and videotaping |
| 9. Construct and use well made testing instruments | Student evaluations and test item response |
| 10. Articulate problems and strengths in one's own teaching style | Student evaluations and videotaping |
| 11. Establish grading guidelines | Student evaluations |

teacher interaction and discussion techniques. Select economic education and educational literature is assigned to seminar participants as outside reading. All of this is intended to provide the *GSIs* with a working knowledge of pedagogical skills and techniques which they will hopefully try in their undergraduate classrooms.

### *B. The Feedback System*

A series of feedback processes are designed to reinforce the teaching abilities and skills presented to the *GSIs* in the seminars. These processes also give the *GSIs* an opportunity an analyze systematically their own teaching performance from the students' point of view. Each *GSI* is encouraged to assess his or her teaching performance on the basis of data collected from three feedback sources—i.e., a videotape observation system, student evaluations of the instructor via the Purdue Rating Scale for College Instructors, and test analysis aimed at evaluating content and application coverage.

The *GSIs* receive primary feedback on their actual teaching abilities by way of prearranged classroom videotapings of their instructional performances. Each *GSI* is videotaped in his or her undergraduate classroom at least three times during the fall quarter. The classroom videotaping of the *GSI* is coordinated by another experienced senior graduate student. This graduate student is also responsible for critiquing each *GSI's* videotape and assisting the *GSI* in spotting weak teaching practices which show up on the videotaped classroom presentation.[5]

To assist in reviewing and critiquing, two procedures and instruments were developed. Prior to each class designated for videotaping, the *GSI* completes a questionnaire directed to the objectives, content and techniques expected to be covered during the class period. This information is subsequently reviewed and compared with the videotape during the critiquing session.

The second instrument was constructed so as to measure actual instructor performance from the videotape. Prior to the review session with each instructor, the graduate student critiquer previews and codes each tape at twenty-second intervals according to a specially adapted observation scheme which measures (a) the

[5] Michael K. Salemi and Becker (1974) provide a videotape demonstration of the critiquing process.

method employed—lecture, question/problems, discussion, other, (b) the learning objectives—knowledge of facts, theoretical concepts, exposition on theory, simple application, complex application, and (c) the verbal and nonverbal expressions—supportive, receptive, neutral, unreceptive, disapproving. The data are then summarized and presented to the *GSI* during the review session.

The data from this latter instrument have proven valuable in at least two regards. Instructors, like students, respond to those things which are being measured. Secondly, the instrumentation is able measurably to confirm or reject those things the instructor says (thinks) he is doing in his classroom. It also reinforces the reviewer's intuitive critique and comments.

Using the standardized procedures and instruments developed, approximately two hours are spent with the individual instructor reviewing and critiquing his or her tape. This method of feedback gives the *GSIs* immediate peer reaction to their actual teaching performance.

The *GSIs* receive additional feedback on their teaching performance from student evaluations both during and at the end of each quarter of instruction. The 28 question Purdue Rating Scale for College Instructors is administered by the *GSIs* and processed by the Center for Economic Education. The printout given back to the individual *GSI* contains (1) a numerical student rating for each question, (2) a numerical student rating for each of five instructor characteristics measured by the Purdue form—personal, objectivity, exposition skills, tests and grading, subject matter knowledge—and (3) a range of average characteristic scores for all instructors over the past four years. The questions are all posed in such a fashion as to give implicit description for appropriate corrective action. This method of feedback gives the *GSIs* a comparable measure of their performance as perceived by students.

A third method of feedback which the *GSI* is taught to use is test analysis. The *GSIs* are taught in the seminars not only to use classroom tests to assess the achievement of their students but also to assist their own teaching performance. Each *GSI* is encouraged to use a variant of discriminant analysis to judge his or her teaching performance from classroom tests. In addition, the *GSIs* are taught to evaluate teaching output in terms of their cumulative students' test achievements, their colleagues' students' achievements and nationally normed student test results. This method of feedback gives the *GSIs* information which is directly related to the cognitive domain effects of their teaching.

Today, after five years of development, the seminar and three part feedback process are complementary inputs to the total teacher training program in the Department of Economics. Graduate students who are currently participating in the program may receive credit for their efforts under a graduate economics course number. The program is able to accommodate from six to fifteen new graduate students per year.

## II. Evaluation

Although there is no recent hard data on the effectiveness of the total training program described above, there is evidence from an earlier prototype program which suggests its effectiveness. Lewis and Charles C. Orvis (1973) carried out a controlled experiment in the 1971–72 school year to evaluate the impact of the initial University of Minnesota teacher training program.

The experiment used a control group of 323 fall quarter principles students (in 14 sections) and an experimental group

consisting of 438 matched winter quarter principles students (in 14 sections) with seven randomly selected and common graduate student instructors. The experiment was designed in such a way that the *GSIs* were not provided with any assistance or training during the fall term. However, during the winter quarter these same *GSIs* were systematically exposed to the department's training program.

Using ordinary least squares regression analysis, Lewis and Orvis included the standard educational regressors (age, sex, American College Testing Service score, grade point average, prior knowledge in economics, and student evaluations) with the student performance data collected. They reported that as a result of the training system student performance, as measured by the Test of Understanding in College Economics (*TUCE*), and instructor performance, as measured by the Purdue Rating Scale for College Instructors, both increased significantly. It was also found that the instructor performance ratings, as measured by student evaluations on the rating scale, associated highly with student performance on the *TUCE*.

## III. Summary

Writing off development costs as sunk cost (borne in part by special grants), the maintenance cost of the Minnesota teacher training program is not high. Variable cost is mainly dependent on the number and type of faculty and *GSIs* assigned to the program. At its present operational level with fifteen participants, only five major variable inputs are needed for maintaining and monitoring the system: (1) the senior faculty member to meet with the seminar and graduate student coordinators for approximately fifteen hours each quarter, (2) an undergraduate student with a quarter-time appointment for the videotape recording of the class sessions, (3) an experienced graduate student instructor with a third-time appointment in economics for scheduling, previewing, and critiquing each class session videotape, (4) an experienced graduate student with a third-time appointment for handling the logistics and demonstrations in the seminars, and (5) an eighth-time secretary to handle form processing and clerical responsibilities. These variable costs amount to about $9,000 per year. The fixed cost of videotape equipment is extremely low when amortized over a six-year period (about $500 per year). On a per graduate student basis, these costs are in line with other graduate course costs at the University of Minnesota.

The Department of Economics at the University of Minnesota has found the benefits to undergraduate students as well as to graduate student instructors outweigh the costs involved in the teacher training program. It is not surprising, therefore, that the history and geography departments at the University of Minnesota have recently adopted this program. Similarly, the graduate departments of economics at Florida State, Harvard, Indiana, Nebraska, Purdue, Wisconsin, and Yale have recently adopted forms of the program described in this paper. They have all joined the University of Minnesota in the Teacher Training Program for Ph.D.s in Economics sponsored by the Joint Council on Economic Education in cooperation with the Committee for Economic Education of the American Economic Association. Surely, other departments of economics and graduate schools can justify instituting similar teacher training programs.

# On Teaching Teachers to Teach

*By* STEPHEN H. LONG*

The purpose of this paper is to evaluate one implementation of the American Economic Association-Joint Council on Economic Education (*AEA-JCEE*) teacher training program. I shall briefly describe the University of Wisconsin version of the training program for graduate students, assess its strengths and weaknesses, and conclude with some thoughts about how we might alter our approach to teaching economists to teach.

The "Seminar on the Teaching of College Economics" began in the 1973–74 academic year. I was among the fifteen participants who joined the seminar which met once each week for one semester. Our studies encompassed course planning (including instructional objectives and task analysis), course implementation (lecturing, discussion techniques, and audio-visual materials), and evaluation of students and teachers (construction of tests, philosophy of grading, student evaluations of faculty, and critiques of video-tapes of seminar participants). The premise upon which the program was based was "whether or not great teachers are born (as opposed to made), most teachers can be trained to become better teachers." I believe this is true and there are some systematic data to support this proposition, in addition to the subjective evidence reported here.[1]

Interestingly, one of the most important benefits of the seminar had nothing to do with the content that has been described. Out of our studies and conversations came a kind of self-consciousness about the process of teaching. We became acutely aware that there existed alternative technologies for producing "Economics XYZ" as described in the catalogue of our first employer, ranging far beyond the choice of the appropriate text. Not only were we thinking about teaching, but we were talking about teaching—which for many of us was an important departure from the preoccupation with research fostered by graduate school curricula. One participant described this outcome as "consciousness raising." Some participants of the seminar are now, two years later, continuing to correspond by exchanging syllabi, exams, problem sets, and ideas about teaching.

A second important outcome results from the study of instructional objectives. There appears to be considerable agreement among the Wisconsin participants that this was the most useful seminar topic. Planning by stating goals in terms of demonstrable student outcomes focuses attention not on the content of the course, which is the stuff of graduate students' training, but on the object of instruction, the student. Commenting on the instructional objective approach, a former Wisconsin participant recently wrote: "I find myself constantly returning to questions

* Assistant Professor of Economics, Franklin and Marshall College. I am grateful to W. Lee Hansen for numerous discussions on the Wisconsin "Seminar on the Teaching of College Economics," and for sharing his 1973–74 students' written evaluations of the seminar. Jon Christianson, Robert Hutchens, Jack Mutti, and Thomas Pender kindly shared their thoughts on the seminar's influence on their teaching, two years after completing the course. Their comments have influenced this evaluation.

[1] Darrell R. Lewis and Charles C. Orvis (1973) present data on the Minnesota teacher training program which was effective in increasing pre-post *TUCE* differences and subjective student ratings of instructors.

of [instructional] objectives in planning courses, selecting textbooks, preparing lectures, etc."

Another significant impact of the program was the creation of a research strategy toward teaching. That is, our teaching is something to be studied and evaluated—not in a casual way (e.g., "I tried a new programmed text this semester and I think my students' essays were better")—but in a formal way, using all the expertise we bring to bear on other research questions. The seminar introduced us to the developing body of research on economic education and acquainted us with some evaluation instruments, including the Test of Understanding in College Economics (*TUCE*) and a number of forms for student evaluation of instructors.

Having developed these important general attitudes—that is, a self-consciousness about the teaching process, an appreciation of the merits of well-articulated instructional objectives, and a desire to carefully evaluate outcomes—the core material of the teacher training program proved useful in our teaching. Helpful tips on leading discussions, writing exams, and performing other instructional procedures were available from the reading materials or presented in class. But rather than describing these details, let me turn to some problems of the seminar.

All teachers must suffer from the problem of heterogeneous student backgrounds, and teaching teachers was no exception. Of the first seminar group of nine, six members were not currently teaching. Furthermore, six had previously taught or were currently serving as teaching assistants for a total of one semester or less. A tension developed between those who had taught more or who were not currently teaching and those who were teaching for the first time. The former exhibited a greater tolerance for abstract issues (e.g., philosophy of grading) while the latter were anxious for information that might be immediately applied in their classrooms (e.g., how to get a discussion started). A number of participants felt that a group having had the same amount of teaching experience would lead to better discussions. For those who had never taught, the seminar's role was primarily one of providing a perspective on teaching and sources for future reference, since many of the teaching skills required active practice to be understood and remembered. Another potential problem of our enrollment stemmed from the fact that participation was voluntary. It is likely that the participants were those students who were most interested in teaching. While they may have been the most receptive to training, they may also have needed it least among all the graduate students since they were more likely to pick up the material independently. Should we require participation by all graduate students, by all those who teach while in graduate school, or at least create incentives for participation?

Another concern of the participants was the nearly exclusive focus on the principles course. Some felt that examples and exercises should have been drawn from courses at the intermediate and advanced levels as well. The question here is whether or not there are important but different teaching problems at different levels. The teacher training program has been designed to focus attention on the various approaches or technologies for getting a specified body of material across to students. It emphasizes the principles course since it is most common to all participants and, some have argued, is the hardest economics course to teach.

The final source of difficulty was that some topics were given too much time, while others were ignored. Task analysis, a procedure for identifying the sequenc-

ing of material for presenting a concept, was seen as useless by a majority of the participants, at least as an improvement over common sense. Among the topics not covered in our seminar were choosing textbooks, managing teaching assistants, particular techniques for classes of varying size, showmanship, and treatment of academic dishonesty. After I moved to my present position in a liberal arts institution, I became increasingly aware of other issues which had been neglected, including the design of an undergraduate economics curriculum, the benefits and costs of team teaching, and broader philosophical issues of content. What occurs to me, however, is not that a program to train graduate students to teach can encompass all these issues, but that the appropriate model for teacher training may have two parts: (1) the seminar for graduate students, to provide the techniques most needed in the short run to "survive" the first few semesters of teaching, and (2) a follow-up seminar for previous participants two to four years out of graduate school, to treat the broader questions which are likely to arise only with experience.

Finally, I must mention that my title "On Teaching Teachers To Teach" purposely does not exclude the possibility of making the *AEA-JCEE* materials available to more experienced economists as well, perhaps through intensive summer workshops. As the demographics of academe lead to lower mobility, institutions may be expected to increase investment in the general teacher training of their older personnel. As a veteran of an *AEA-JCEE* seminar and an institution-sponsored faculty development program for persons of all disciplines, I strongly recommend that the profession continue its present efforts and that it extend their scope to include more experienced economists.

# One Participant's View of the Teacher Training Program

*By* Richard B. Hansen*

During the spring semester of 1974 the Department of Economics at the University of Nebraska offered a teaching seminar for graduate students which was based on a pilot Teacher Training Program sponsored by the Joint Council on Economic Education. When I was first asked to present my views as a participant in this seminar, I had mixed emotions concerning the insights I would be able to offer. I felt very strongly that I had benefited from the seminar and yet, in retrospect, it almost seemed that what I had been taught about teaching was common sense. Then, as I reflected on eight years of being a college student, I decided that most of what I had learned was, to use an analogy from economics, no more obvious than the fact that public debt differs from private debt, i.e., what I had learned was obvious only after it had been pointed out.

While I cannot furnish hard evidence, I will attempt to explain why I feel that the seminar was beneficial by relating some of the ways in which it influenced my teaching. My examples will be set in the context of the introductory economics course which served as the focal point of the seminar.

Our first seminar meeting dealt with the importance of establishing course goals and communicating them to the students. My own experience as a student reinforced the importance of this since I took my first economics course thinking that I was going to learn how to make money. As the course progressed, I got the same feeling I had had when I surreptitiously read *Lady Chatterly's Lover*—I kept wondering when I was going to get to the good part! In order to avoid this kind of misunderstanding, I tell my students on the first day of class that my primary goal is to help them become better informed citizens and that in order to attain this I want them to learn to apply economic theories and facts. Identifying what I want to accomplish in the course not only tells the students what to expect, it also helps me in selecting the topics that I cover and in determining how I treat those topics, e.g., I spend at least a full class period trying to convey the basic idea of economic efficiency and then ask the students to apply the concept to the present debate over the efficiency of pollution control devices.

A closely related point that was made clear in the seminar is the idea of telling the students what they are expected to learn. Formally, this entails the use of instructional objectives which, simply put, are specific statements of what the teacher wants the students to learn and how they are expected to demonstrate this learning. While I do not presently have time to construct properly written objectives, I do attempt to use the rationale behind them in several ways: first, by distributing study questions prior to each hour exam; second, by giving weekly quizzes covering material which I feel is important; and third, by posing questions in class which, as I tell the students, are indicative of

* Ph.D. candidate, University of Nebraska-Lincoln.

the type of question which I want them to be able to answer.

Another useful topic treated in the seminar was learning theory. In a very lucid and nontechnical article on the subject, G. L. Bach points out that learning involves the acquisition or modification of behavior so that students should be able to "do" economics if they have learned it. Additionally, Bach discusses the importance of motivation, relevance, clarity, feedback and reinforcement to the learning process. One strategy that I have developed which incorporates most of these elements, and with which I have had some success, is a weekly quiz. One class period in advance, I pose a question that requires the application of previously presented material to a contemporary or historical situation. By letting the students use what they have learned, this procedure demonstrates the applicability of economics (relevance) and encourages the students to learn the material (motivation); additionally, it provides repetition (reinforcement) and gives me the opportunity to let the students know how well they are doing (feedback) so that they can correct any deficiencies (or, as happened once, so that I can correct a deficiency in my presentation).

In terms of the number of ways in which my teaching was influenced, an article by Phillip Saunders and the accompanying seminar session on lecturing was dominant. Aside from convincing me that lecturing is a skill which can be developed, rather than an innate talent, the article provided many ideas which I have incorporated in my lectures. Let me mention a few. For one thing, I begin each class period by putting an outline of the material I want to cover on the blackboard. Second, after I have finished my presentation of a topic I usually pose a question which is intended to verify the student's comprehension of the material; additionally, this procedure gives me the opportunity to appraise my presentation and correct any inadequacies. Third, I often make notations to myself after class concerning aspects of the class that were especially good or poor so that I can make any indicated adjustments the following semester. Fourth, I have lost my reluctance to inject humor occasionally into my lectures (though, of course, humor is no substitute for preparation); this helps to put me at ease and, judging from my evaluations, creates an open atmosphere for the students. Finally, I have borrowed the idea of asking the students to complete an evaluation form after four weeks of class so that I can make any needed adjustments early in the semester (students indicate that they appreciate this).

Test construction is another area in which I feel more confident as a result of the teaching seminar. Of course, having fairly well-defined objectives in mind makes test construction a much easier task. And now that I am aware of the strengths and weaknesses of essay and multiple choice questions, I can more easily select the kind of question better suited to the topic and the level of understanding which I am testing. With respect to multiple choice questions, I have made use of a procedure called item analysis which reveals how many students selected each possible response and also indicates how students who performed well on the whole test fared on each question relative to those students who did poorly on the test. I have rewritten questions after discovering that only one or two students opted for a particular answer or finding out the "poor" students did better on a question than the "good" students.

In addition to these relatively specific examples, there are some broader, more general ways in which the seminar influenced my teaching. For one thing, I approach the introductory course as

though it were the only economics course the student would ever take; for me this has meant sacrificing theoretical rigor for realistic application. Second, I limit the amount of information which I cover in an effort to ensure that the students have a firm understanding of basic economics. Finally, and perhaps most importantly, I have become more interested in teaching as a result of taking the seminar; indeed, probably the most important lesson I learned came from an article by Ben Lewis which taught me to be unafraid of failure and unsatisfied with success.

It would be an error to conclude from what I have said that the teaching seminar was perfect. Considering that it was an inaugural venture when I participated, it is perhaps not surprising that there were shortcomings. For example, each participant was videotaped once in his classroom; since this is an excellent means of providing feedback to the novice instructor in his teaching, it seems to me that three or four tapings would be preferable (Nebraska now does three tapings). Student-teacher relations is another area to which I feel more time should have been devoted. Also, I think that the two hour session we had on audio-visual technique was too long (though certainly some familiarity with this technology could be useful).

In conclusion, I think that the Teaching Seminar was a worthwhile experience because it increased my interest in economic education and exposed me to techniques which I feel have improved my teaching. Considering the amount of time that our profession devotes to teaching a very important subject and the paucity of systematic effort generally given to improving instruction,[1] I would suggest that every Ph.D. granting department consider instituting this kind of program.

[1] The efforts of the Joint Council on Economic Education and the Committee on Economic Education of the American Economic Association represent important exceptions to this generalization.

# INFORMATION AND MARKET STRUCTURE

## Information and Monopolistic Competition

*By* STEVE SALOP*

Information gathering and transmission have been gaining a larger role in the economy over time. M. Porat (1975) has estimated that the production, processing and distribution of information goods and services account for over a quarter of *GNP*. George Stigler (1961), George Akerlof (1970), and the papers in Edmund Phelps's volume (1970) showed the presence of imperfect information gives firms market power at least in the short run and often in the long run as well. Peter Diamond (1971) showed that the existence of costly information gathering led to an equilibrium in which each small firm charged not the competitive price but rather the monopoly price. Later papers have expanded Diamond's work for markets with different production and information gathering and transmission technologies. These papers find that if information is costly, each small firm obtains market power, and the equilibrium (if one exists) is characterized by prices above competitive levels and sometimes price dispersion as well. *The relevant market structure with imperfect information is not perfect competition but rather monopolistic competition.*

### I. The Basic Competitive Framework

There are a potentially infinite number of identical firms which can produce a homogeneous commodity from a production technology with fixed cost $T$ and increasing marginal cost function $MC(q)$. Thus, the average cost curve is U-shaped, attaining its minimum at $(p^*, q^*)$.

There are a large number of consumers $L$, who wish to consume this commodity. We begin by assuming that each consumer has an identical perfectly inelastic demand for one unit of the commodity at all prices below $p^m$. (Thus, $p^m$ can be interpreted as the dollar valuation of the commodity's marginal utility. It is most convenient to think of this commodity as a durable which is bought only once by each consumer.)

A monopolistic producer surely charges a price equal to $p^m$. If there is free entry into this market, new firms drive down the price until it falls to the competitive price $p^*$. No price dispersion is possible since each perfectly informed consumer will approach the lowest priced firm.

### II. Imperfect Information

In a Lancaster framework, the utility services derived from any commodity is a complex function of the characteristics that specify the commodity. The net utility surplus equals the utility services derived less its price. Given a choice among competing commodities, the "best buys" are those brands with highest net surplus.

Initially, a consumer has imperfect expectations regarding the net surplus of each good. These imperfect priors derive from his general knowledge and past information gathering and experience. It is useful to think of this as a dynamic learning process. The prior can be thought of as a probability distribution of the net surplus of a commodity. The distribution may

* Federal Reserve Board. These are the views of the author and should not be interpreted as the views of the Board of Governors. I am grateful to my collaborator, Joseph Stiglitz, and L. J. Dillard, M. Porat, and the editorial assistance of G. Edelen.

be an unbiased estimate of the actual net surplus (rational expectations) or may be biased due to incorrect extrapolation of the past, unseen commodity specification changes, past sampling realizations, false claims, or general ignorance. The formation of the prior is made more difficult since the relevant questions may not even be known until after some information is gathered.

The cost of information gathering will depend on the technology of information production and diffusion, the type, complexity and number of commodities, and the consumer's priors and preferences. These will define the speed of the learning process. Information gathering improves the quality of the posterior distribution. The expected value of information can be viewed as the increase in expected net surplus from the information. The effective cost of information includes its resource and nonpecuniary costs and will depend on the consumer's cost of time, preferences, analytic ability, experience and understanding of the market. For example, bargain hunters and (presumably) economists have low costs.

Depending on its cost, complete or incomplete information may be gathered. By complete information, we mean information that enables the consumer to purchase the best buy available. By incomplete, we mean that his expected net surplus will lie somewhere between the average and the best buy. For incomplete information gathering, the consumer must choose the sample size, minimum acceptable net surplus level, or reservation price.

Nelson (1970) contrasts two modes of information gathering, "experience" and "search." By "experience," we mean the knowledge obtained from actually using the commodity. This information may be gathered from personal use or from the experience of acquaintances (shared information). It is more likely to be utilized for inexpensive nondurables with unknown quality that are consumed each period. Experience information is generally incomplete, since every commodity is not sampled, and, in addition, the actual performance of a brand may be a random variable. By "search," we mean sampling before purchase by studying consumer magazines, visiting or phoning stores, reading advertisements, etc. Price information may be generated by search. In principle, search may yield complete information. For example, one could envision a magazine like *Consumer Reports* that publishes *all* the relevant information; a truthful guarantee has much the same effect.

There are important interactions (externalities) among consumers in the process. For example, if a consumer (having had one economics course) thinks that search by other consumers keeps the market honest so that price reflects quality, he need gather no information himself but will purchase the commodity with the greatest market share (John Conlisk and Dennis Smallwood). Alternatively, if a consumer believes in the Lemon's Principle, he will drop out of the market altogether (Akerlof).

Before analyzing this market, let us ask the question of why low cost consumers do not arbitrage the information differences away. Stated another way, since the marginal cost of distributing the information is nearly zero, why won't competition among information producers drive down the price? First, consumers face the same information problem with respect to information sellers as they do with respect to the commodities themselves. Each magazine must be evaluated and its content processed and analyzed. Furthermore, since the dissemination of the information by each magazine exhibits decreasing average costs, the information industry cannot be competitive in long-run equilibrium.

### III. Equilibrium

We now analyze the behavior and equilibrium price structure of this commodity market. Initially, the dynamics of the learning process are ignored. An equilibrium in this market is $n$-prices $p=(p_1, p_2, \ldots, p_n)$ each charged by a proportion $\beta=(\beta_1, \beta_2, \ldots, \beta_n)$ of the $N$-firms in production such that the following price and entry competition conditions are satisfied:

(1) *Price Competition* (*Maximum Profits*). Each firm chooses the price (and quantity) which maximizes its profits given its knowledge regarding the behavior of consumers and other firms (i.e., its demand curve).

(2) *Entry Competition* (*Zero Profits*). No new firm wishes to enter the market.

The exact specification of a firm's demand curve depends on the informational and strategy assumptions we make about firms. We will assume that a firm chooses a price given (i) the prices *chosen* by the other ($N$-1) firms and (ii) the search *rules* of consumers. Thus, a firm is a "Nash" competitor vis-à-vis other firms and a "Stackleberg" competitor vis-à-vis consumers. Condition (2) is the free entry assumption. We assume that entry occurs if profits are positive; hence, it is the zero profit condition.

In order to demonstrate the existence of the equilibrium, we follow the method of proposing a *potential* equilibrium set of $n$-prices $\hat{p}=\{\hat{p}_1, \hat{p}_2, \ldots, \hat{p}_n\}$, proportions $\hat{\beta}=(\hat{\beta}_1, \ldots, \hat{\beta}_n)$, outputs $\hat{q}=(\hat{q}_1, \hat{q}_2, \ldots, \hat{q}_n)$, and a number of firms-$\hat{N}$, and then see if any of the existing $\hat{N}$-firms wishes to change its price or if any potential entrants wish to enter. A potential equilibrium is an actual equilibrium if both deviant behavior and entry are unprofitable. An equilibrium can be pictured as in Figure 1.

The minimum price ($p_1$) will never be below the competitive price, for that would yield negative profits. Nor will the highest price be above the monopoly price. The exact specification of the equilibrium will depend on the production technology, the information gathering technology, and the joint distribution of consumers, utility valuations and search costs.

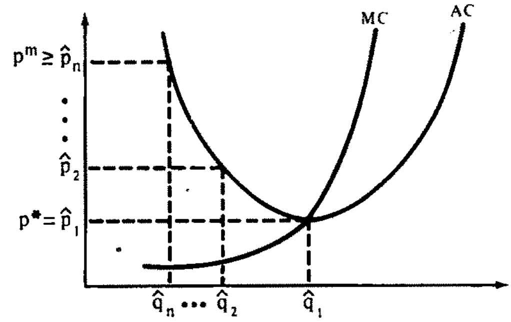

FIGURE 1

A simplified example can highlight the properties of the equilibrium. Assume that $L$-consumers all have identical valuations $p^m$, known with certainty. Prior price expectations are rational but limited. Consumers know the correct set of prices and proportions $\{p, \beta\}$, but a priori, they lack the knowledge of which firms charge which price. (This assumes away lemons and two-armed bandits.) For a cost $c_i$, consumer $i$ can purchase complete information from *Consumer Reports* in the form of the complete price-location correspondence. There are only two groups of consumers, a proportion $\alpha$ with cost $c_1 \geq 0$ and a proportion (1-$\alpha$) with higher cost $c_2 > c_1$. In spite of overwhelming empirical evidence to the contrary (A. Tversky), we assume consumers gather information in a rational, maximizing manner.

If both groups have perfect information ($c_1=c_2=0$), the competitive equilibrium ($p=p^*$) will obtain. If there are enough perfectly informed consumers ($c_1=0$, $\alpha$ high), the competitive equilibrium can still obtain in spite of $c_2>0$. This is an example of the externality informed consumers give to the uninformed. The weight of their search keeps the market competitive.

If both groups have positive cost, the competitive equilibrium cannot occur. A deviant firm could raise its price slightly above the competitive price and lose no customers. The only possible single-price equilibrium is the monopoly price, with entry competition driving profits to zero at this high price (Diamond). That equilibrium will obtain only if information costs are large for both groups. At this equilibrium, in order to induce consumers to pay the cost of discovering its location, a deviant firm would have to follow the unprofitable strategy of charging a price below the competitive price.

If lowering price to induce search is profitable, a two-price equilibrium (*TPE*) will obtain in which a proportion $\beta$ of the firms charge the competitive price ($p_l = p^*$) and the rest charge a higher price no greater than the monopoly price ($p^m \geq p_h > p^*$). Every type-1 consumer purchases complete information and pays the lower price. The higher price has the property that the type-2's do not find it worthwhile to purchase information. However, a proportion $\beta$ of the type-2's are lucky and randomly select a low-priced firm. Entry competition occurs until every firm makes zero profits.

When only complete information can be purchased, a *TPE* obtains even when there are many types of consumers (Salop and Stiglitz). In contrast, when incomplete information can be purchased, there will be as many prices in equilibrium as there are types of consumers (Gerald Butters, Peter von zur Muehlen).

If costs have little dispersion and are not too high, there is no *TPE* either. However, a single "limit price" $p^L$ exists with the following property. A deviant firm could increase its profits by raising its price above $p^L$. But if it does act in this short-run interest, it will destroy the equilibrium by inducing other firms to drastically cut price to induce search. Prices may begin to oscillate between the competitive price

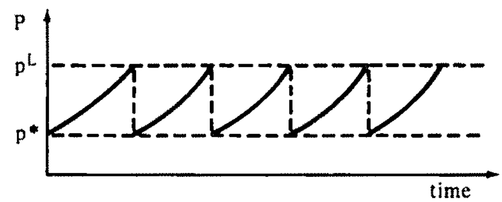

FIGURE 2

$p^*$ and the limit price. The exact dynamics will depend on the dynamic learning process by consumers and firms. In general, prices may creep up slowly to above the limit price which induces a price war down to $p^*$, only to again begin the upward creep. (See Figure 2.) The frequency and regularity of the cycle will depend on the time adjustment speeds of price changes, entry, and the learning by consumers.

An interesting example of this process is that of dynamically captive markets. Suppose consumers have better information regarding the brand they are now consuming than about other brands they consumed in the past or have never consumed. This asymmetry in information gives each firm market power over its current risk-averse customers since there are effectively "moving costs" of uncertainty from changing brands. If these moving costs are high enough, every firm can act like a complete monopolist over its segment of the market. Some deviant firm may find it profitable to subsidize these moving costs by charging a lower price. It gains customers who in turn become its captive as the information from their past experience decays. Hence, the deviant firm can creep its own price upwards towards the monopoly price.

Y. Shilony shows that a mixed strategy equilibrium in which each firm changes its price every period results from such a "captive market model," even when the commodities are nondurables bought every period. No firm's price ever settles down, so imperfections in information remain forever. This analysis also has the interesting feature that the firms could form a

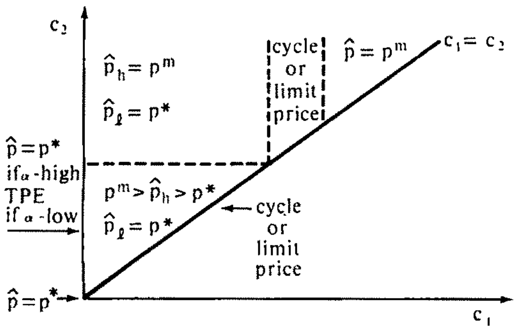

FIGURE 3

"noncooperative cartel" that needs to collude only once to set the random pricing rules. Once the cartel is begun, no single firm will ever find it profitable to cheat by deviating from the rule.

The various types of equilibria discussed are summarized in Figure 3.

### IV. Advertising

The firms themselves may engage in information transmission through truthful advertising and guarantees. This does not change the basic result. For example, suppose expensive large ads and inexpensive small ads are available, type-1 consumers are likely to notice both sizes, and type-2 consumers are likely to see only large ads. Then, firms that run large ads incur higher fixed advertising costs, charge a higher price and sell only to type-2's. On the other hand, suppose a firm sends ads out randomly, and each consumer chooses the firm with the cheapest advertised price from the ads received. In this model, price dispersion results even if consumers are identical (Butters). In both approaches, the highly advertised brands have higher costs and charge higher prices in equilibrium. Of course, this equilibrium result is different from the short run practice of a low priced deviant advertising its lower price. False advertising, bait-and-switch, dishonored warranties and other forms of fraud have also been assumed away in this analysis, though they are certainly profitable in the short run, and in the long run too if there are new suckers (ignorant consumers) born every minute.

### V. Price Discrimination

So far we have focused on price dispersion arising from search cost dispersion in which poorly informed consumers pay higher prices. When consumers differ in their valuations as well, monopolistic competition will generate price discrimination against consumers with both high costs and high valuations. Low valuation-high cost consumers will not purchase. A monopolist may also use dispersion in search costs to price discriminate against unidentifiable consumers with inelastic demand curves (high $p^m$'s here). If he permits price dispersion (through unadvertised specials or contrived heterogeneity), the high cost consumers will search less and hence pay higher effective prices on average. If these customers have more inelastic demand, then price dispersion acts as a price discriminating tie-in of search (a "bad") with the commodity he produces (Salop).

### VI. Competition vs. Welfare

The existence of many similar brands tends to increase effective search costs. Suppose a consumer must purchase a brand in order to gauge its utility (an "experience" good). Optimal search would consist of sampling brands *without replacement* until an acceptable one is found. In this case, entry competition has two countervailing effects. The usual entry effect increases choice and decreases prices. On the other hand, in sampling without replacement, small population sizes are preferred to large ones. For example, suppose there are 3 firms and a consumer evaluates the net surplus of these 3 brands as {5, 10, 15}. If he samples without replacement 3 times, he will certainly attain the maximum utility level of 15. If the number of firms doubles to 6 and the distribution of

utility levels remains identical (i.e., {5, 5, 10, 10, 15, 15}), then a sample of size 5 is required to obtain a level of 15 with certainty. A sample of size 3 will give expected maximum utility of only 13.1. Thus, the tradeoff between search intensity and utility level worsens, just as it would from an increase in effective search costs. In equilibrium, the increased cost tends to raise prices, *ceteris paribus*. The net effect of increased competition may be either to raise or lower prices. Thus, there may be a tradeoff between competition and static welfare.

# Information and Competitive Price Systems

By SANFORD J. GROSSMAN AND JOSEPH E. STIGLITZ*

Although the price system is conventionally praised as an efficient way of transmitting the information required to arrive at a Pareto optimal allocation of resources, the context in which the price system is usually discussed is not one in which the informational efficiency of the price system can be properly evaluated. Questions of how the price system leads the economy to respond to a new situation, how it conveys information from informed individuals to uninformed individuals, and how it aggregates the different information of different individuals, are never directly attacked.

In a series of papers (Grossman 1975a, 1975b, Grossman and Stiglitz 1975, and Stiglitz 1971, 1974), we have attempted to remedy this deficiency. It is the object of this paper to draw attention to some of the more fundamental implications of our approach and to use it to assess the meaning and validity of the efficient market hypothesis. Although our discussion will accordingly focus on the capital market, the kind of analysis developed here is applicable to any competitive market subject to random shocks.

## I. Prices and the Transfer of Information

The basic idea behind our analysis[1] may be illustrated by the following example:

Assume there are two assets, one safe and one risky, and that the return to the risky security $r$, depends on a random variable $\eta$, which can be observed at a cost, and another, unobservable random variable $\epsilon$:

$$r = \eta + \epsilon, \tag{1}$$

where $\eta$ and $\epsilon$ are independent, normally distributed random variables. Knowing $\eta$ reduces but does not eliminate the risk associated with the asset. The per capita demand, $X_I$, for the asset by those who are informed of $\eta$ will depend both on the price of the asset and the value of $\eta$.

$$X_I = X_I(p, \eta). \tag{2}$$

We assume that $\partial X_I/\partial\eta > 0$ and $\partial X_I/\partial p < 0$. Equilibrium each period requires that demand equal supply:

$$\lambda X_I(p, \eta) + (1 - \lambda)X_U(p) = X^s, \tag{3}$$

where $X_U$ is the per capita demand of the uninformed, $X^s$ is the per capita supply and $\lambda$ is the fraction of the individuals who are informed. Uninformed individuals observe only price, but from the price they may be able to infer $\eta$. For instance, if the stock of the resources were fixed, the uninformed individual can infer that a higher $p$ is associated with a higher $\eta$, since an increase in $\eta$ increases informed demand, and thus the price. Since there are no other stochastic elements in this model, there will be precisely one $\eta$ corresponding to any $p$. Hence, the conditional distribution of $r$ given $p$ is the same as the conditional distribution of $r$ given $\eta$. Thus, the price system conveys all the information from the informed individuals to the uninformed.

Now, let us introduce some further randomness; e.g., in the stock of the risky asset or in the demand functions of informed or uninformed individuals. Then the price

* This work was supported by National Science Foundation Grant SOC74-22182 at the Institute for Mathematical Studies in the Social Sciences (*IMSSS*), Stanford University. The authors are also indebted to the Dean Witter Foundation for financial support.

[1] See Grossman and Stiglitz (1975) for proofs and a detailed analysis of the model described by equations (1)-(4).

may be high because $\eta$ is high, but it may be high because the supply of the risky asset is low, or because informed individuals' demand functions have shifted upwards. Hence, corresponding to any $p$, there is a *distribution* of possible values of $\eta$. The price system conveys some information, but does not transmit all the information from the informed to the uninformed: on average, when the price is high, the return is high (i.e., $\eta$ and price are correlated) but the price is a *noisy signal;* that is $p$ and $\eta$ do not contain the same information about $r$.

Assume that the source of randomness is the supply of the risky asset. (We shall use this example through the rest of the paper.) Then, from (3), the equilibrium price will depend on $\eta$ and the stock of the risky asset, $X^s$; write $p=p(\eta, X^s)$. Solve for $\eta$ as a function of $(p, X^s)$ as, say, $\eta=\mathrm{t}(p, X^s)$. Using (1):

$$r = \mathrm{t}(p, X^s) + \epsilon. \tag{4}$$

The distribution of $(X^s, \epsilon)$ induces a distribution on $r$ for a given $p$. Since the uninformed observe $r$ and $p$, they come to learn the conditional distribution of $r$ given $p$. When they observe a $p$, they use this distribution to determine the expected utility from purchasing a given amount of the risky asset; $X_U$ is chosen to maximize expected utility. This is how the uninformed individual's demand function in (3) is derived. Finally for this to be an equilibrium, for all $\eta$ and $X^s$, $p=p(\eta, X^s)$ must be a solution to (3). Such an equilibrium entails rational, self-fulfilling expectations.

This is a reasonable condition for long-run equilibrium. If this condition is not satisfied (and the stochastic process describing the returns is stationary),[2] then an individual will eventually observe that the frequency distribution of returns, conditional on the observable variables, is different from the subjective distribution, and accordingly, ought to revise his expectations.

As there are costs of obtaining information, the marginal individual who chooses to become informed must be indifferent to being informed or uninformed, i.e., the increment in expected utility from becoming informed is exactly offset by the cost of the information. In making this calculation, individuals assume that a change in their information (and hence in their demands) would have no effect on prices. This is an adaptation to this context of the conventional Nash equilibrium hypothesis of competitive equilibrium theory.

Since when no one is informed, the price system conveys no information, the value of information about $\eta$ is likely to be high; when almost everyone is informed, the price system is very informative, so the value of knowing $\eta$ precisely is low. Thus, provided the costs of information are positive but not too high, equilibrium entails a fraction, $\lambda^*$, of the population being informed—that $\lambda$ which generates a price solution to (3) such that the marginal individual finds the expected utility to being informed equal to the expected utility of being uninformed.

Some striking features of the equilibrium which we have modeled should be noted. First, it provides a resolution of the following classical conundrum. If markets are perfectly arbitraged all the time, there are never any profits to be made from the activity of arbitrage. But then, how do arbitragers make money, particularly if there are costs associated with obtaining information about whether markets are

[2] One can argue that the limitation of our analysis to stationary stochastic processes is not a serious limitation; economic theory is concerned with identifying, describing, and explaining regularities in economic processes. Economic theory attempts to identify within a particular event those characteristics which it has in common with other events which have occurred. It is these regularities that are described by the stationary stochastic process.

already perfectly arbitraged? The conventional answer is that, when markets are not arbitraged, there are profits to be made, and so equilibrium *must* entail perfect arbitrage; the profits accrue in the process of responding to some unspecified disequilibrium. A particular example of this classical conundrum is presented by the efficient market hypothesis, which argues the prices on capital markets reflect all the relevant information instantaneously.

We resolve this paradox by arguing that there are constantly new shocks to the economy; although each of these shocks may have certain individual characteristics—the company president may be sick, a machine may break down—from the point of view of an analysis of market behavior, we are interested not in these individual characteristics, but in how these shocks affect market returns; and we postulate that we can describe the occurrence of these different shocks, in terms of their effects on returns, by a stationary stochastic process. The capital market must continually adjust to these shocks. We have formulated an equilibrium notion which explicitly takes account of the economy's response to these various shocks. Others have described this as a disequilibrium situation, but have been unable to say much about it.

In the structure we have developed, the market never fully adjusts. Prices never fully reflect all the information possessed by the informed individuals. Capital markets are not efficient, but the difference is just enough to provide the revenue required to compensate the informed for purchasing the information. The equilibrium fraction of informed traders $\lambda^*$ is determined jointly with the informativeness of the price system in such a way as to generate a competitive return to arbitrage.

Perfect arbitrage has one important implication—not all traders need to be informed. The informed traders make prices reflect true values, and the uninformed can simply take advantage of these services provided by the informed. In our analysis this is not true. Indeed, it is only because prices do not accurately represent the true worth of the securities (i.e., the information of the informed is not fully conveyed through the price system, to the uninformed) that the informed are able to earn a return to compensate them for the costs associated with the acquisition of the information.

Those empirical tests of the weak version "efficient market hypothesis" which show there are no gains to be made from looking at current prices and the past performance of the security provide support for our model, which assumes uninformed traders have rational expectations. But contrary to strong versions of the efficient market hypothesis, prices do not fully reflect all available information, in particular, that of the informed; the informed do a better job in allocating their portfolio than the uninformed. "Efficient markets" theorists state that costless information is a *sufficient* condition for prices to fully reflect all available information (Eugene Fama, p. 387). They are not aware that it is a necessary condition as well. But this is a *reductio ad absurdum*, since prices are important only when information is costly. (See Friedrich A. Hayek and Grossman 1975b.) Thus, an individual who throws darts at a dartboard to allocate his portfolio will not do as well as the informed individual;[3] what can be decided by a toss of the coin is not the allocation of the port-

[3] It is still true that if individuals were all identical and purchased the "market basket" of securities, the uninformed would do as well as the informed. Here we assume that the kind of information to make that feasible is not available. If individuals differ in their attitudes towards risk, or in their information structures, even when such a strategy is feasible, it may not be optimal.

folio but whether to be informed or uninformed.[4]

A second important characteristic of our analysis is that there is no proper separation between demand and supply. An increase in supply leads to a lowering of the price; since lower prices *on average* correspond to states in which returns are lower, the lowering of the price leads to a *lowering* of the evaluation of the risky security by the uninformed individuals, and hence of their demand. One cannot describe the equilibrium meaningfully in any period in terms of independently drawn demand and supply schedules, because the demand curves depend on the probability distribution of supply. This has the further consequence that an increase in price may actually increase demand; the presumption for a downward sloping demand curve is much weaker when individuals judge quality by price.

Still a third important and related observation is that prices, in our model, are serving two functions: not only are they being used to clear markets in the conventional way, but they convey information. In this sense, the models we have formulated are closely related to George Akerlof's lemons' model and to Akerlof (1973) and Stiglitz' (1975) analysis of labor markets.

The discussion so far has focused on the decision of whether to be informed or uninformed. There is an alternative way of looking at this question, which may shed some light on an old question discussed by John M. Keynes (p. 156). He suggested that the stock market might be viewed as a beauty contest, where the participants are not concerned with judging who is the most beautiful woman, but with judging who the other judges will believe is the most beautiful woman. Keynes made these remarks with more than a hint of disapproval; our analysis suggests that this may be unwarranted. It may be more efficient for some individuals to obtain information from others—through the price system or by other mechanisms—rather than obtain it directly.

## II. Prices as Aggregators

So far, we have discussed equilibrium in markets where prices convey information from the informed to the uninformed. In some market situations, different individuals have different information, and then the price system may serve to aggregate their information. That is, the demands for a risky security of an individual are affected by his information; total demand and accordingly equilibrium market prices thus depend on the information of all the individuals. In this sense the market price aggregates the various pieces of information.

A simple example may make this clearer. Assume there are a large number of isolated farmers. Each knows the size of his own crop, $y_i$. The size of the crop on any farm at any date is described by

$$y_i = \alpha + \epsilon_i \tag{5}$$

where $(\epsilon_i, \epsilon_j)$ are uncorrelated, $\alpha$ and $\epsilon_i$ are independent, normally distributed random variables with means $(\bar{\alpha}, 0)$ and variances $(\sigma_\alpha^2, \sigma_\epsilon^2)$, respectively. Thus, if $Y \equiv \sum_1^n y_j$, then $E(Y|y_i)$ is just a linear function of $y_i$, i.e., $E(Y|y_i) = h_1 + nh_2 y_i$.[5] Assume that there is a linear demand curve for the crop, so

$$Y = a - bP_s \tag{6}$$

where $P_s$ is the spot price next period. Then the subjective distribution of $P_s$ is normal, with mean $(a - E[Y|y_i])/b$ and a

[4] This is true only if no one has a comparative advantage in acquiring information.

[5] $E[Y|y_i] = n[\gamma\bar{\alpha} + (1-\gamma)y_i] \equiv h_1 + h_2 y_i$

where $\gamma \equiv \dfrac{\sigma_\epsilon^2(n-1)}{n(\sigma_\alpha^2 + \sigma_\epsilon^2)}$.

variance which is independent of $y_i$, $\sigma_p^2$. Since individuals differ in their expectations, there is an incentive to set up a futures market. Assume all individuals have constant absolute risk aversion, $k$. Then their demand for "futures" $Y_i^f$ is given by (where $P_f$ is the futures price):[6]

$$(7)\quad Y_i^f = \left[\frac{\dfrac{a - E(Y \mid y_i)}{b} - P_f}{k\sigma_p^2}\right] + y_i$$

and the market equilibrium requires

$$(8)\quad 0 = \sum Y_i^f = \frac{n}{k\sigma_p^2}\left\{\frac{a - h_1 - h_2 Y}{b} - P_f\right\} + Y.$$

Using (6), we obtain the result that the futures price is a linear function of the spot price:

$$P_f = h_3 + h_4 P_s.$$

It is a perfect aggregator of the information collected by the different individuals, i.e., by observing $P_f$, one can make a perfect prediction of the quantity available in the market and $P_s$.[7]

But there is a fundamental problem; if, as one would expect, individuals eventually come to realize that the futures price is a perfect predictor of the future spot price, then they will no longer base their demands on their own information, but rather base it solely on the market information. Since the futures price predicts the spot price perfectly (with zero variance) there is no need for hedging and there will be no trade. But without trade, there is no market; but without a market; their beliefs will differ. This paradox can be put another way. If the market aggregated their information perfectly, individuals' demands would not be based on their own information, but then, how would it be possible for markets to aggregate information perfectly?

So far, we have discussed some of the basic properties of our approach to equilibrium when information is costly. These models can also be used to address conventional questions related to existence, comparative statics, and welfare.

## III. Existence of Equilibrium Market Breakdown and Thinness

Both Akerlof (1970) and Grossman (1975a) argue that in markets where prices convey information between informed and uninformed traders, there is a possibility of market breakdown associated with a dwindling in the amount of trading. The example of the stock market presented above showed that this could indeed happen: if the price system were fully informative, there would be no differences in beliefs; and if there were no differences in beliefs, there would be no trade; but then it appears that it is prices in markets in which there are no trades which leads to uniformity of beliefs. Although this problem would be alleviated if prices did not perfectly convey information from the informed to the uninformed or if there were motivations for trade other than differences in information (e.g., differences in attitudes towards risk or in endowments), markets still might be thin, i.e., there would be a small volume of trade, and hence markets may be far from perfectly arbitraged.

Situations where markets might be thin or nonexistent need to be distinguished from those in which equilibrium does not exist. In the absence of noise, with costly information, an (Nash) equilibrium does

[6] Profits are $\pi = (P_f - P_s) + P_s y_i$. Then under normality and constant absolute risk aversion $k$, the individual maximizes

$$Y_i^f(P_f - E[p_s \mid y_i]) + E(P_s \mid y_i)y_i - \frac{k}{2}(y_i - Y_i^f)^2\sigma_p^2.$$

Solving for the optimal $Y_i^f$:

$$Y_i^f = y_i + \frac{E[P_s \mid y_i] - P_f}{k\sigma_p^2}.$$

[7] If $1 \neq nh_2/bk\sigma_p^2$, then $h_4 \neq 0$.

not exist,[8] since when one is informed, every individual believes he can become informed, increase his expected utility and not affect the market price. However, when a positive fraction of the population becomes informed the price system is fully informative, so it does not pay anyone to purchase the information.[9]

## IV. Welfare

The evaluation of the efficiency of the market in situations such as those analyzed in this paper is a subtle and difficult question. It is not obvious what the appropriate comparisons ought to be. Two alternative approaches might be delineated. In the *reformist* approach, we take as given the market structure, including the mechanisms for information transmittal. We ask simply, are there too many or too few informed individuals, or, is it desirable to have an information tax or subsidy? Although it is easy to show that the market solution is not, in general, efficient, it is difficult to ascertain whether there is too little or too much information acquisition. There are several effects, operating in different directions: some of the gains arising from *differential* information are private but not social returns, gains that some individuals make at the expense of others; on the other hand, since some information is conveyed by the price system, if that information is socially useful, those who purchase information generate a positive externality to those who do not. See Jerry R. Green (1973) and Stiglitz (1971). Even if there were no differential information, the price distribution does depend on the state of information. To return to our example of Section I, since when everyone is fully informed, price varies with $\eta$ and $X^s$, while when no one is informed, price varies only with $X^s$, it would not be surprising if information increases the variance of prices. Increased price variability is likely to lead to increased uncertainty about the value of one's endowments, and this is likely to lower expected utility. In one example we have analyzed in detail, where individuals have constant absolute risk aversion utility functions and randomly assigned endowments (all individuals having, however, the same endowment distribution), every one is better off if no one is informed than if all are informed.[10]

Finally, if the return to holding an asset for a period is the dividend plus the capital gain, the increased variability in price of the risky asset makes the risky asset riskier; thus, while in general, information reduces the riskiness of a risky asset, this is at least partially offset by this general equilibrium effect.

More fundamental questions are raised by the choice of alternative approaches to

[8] In the case where information is costless, an equilibrium exists; among the set of prices which might clear the market, there is a particular price function which clears it at zero trade and conveys all the relevant information, and this may be considered to be an equilibrium. There is no obvious mechanism for sustaining this particular set of prices, and this is a serious limitation.

[9] There could not exist an equilibrium in which trade occurred even if an individual had a monopoly power over information. For then the uninformed individuals would observe that they would do better not trading with the monopolist than trading with him, and the information-monopolist would simply determine equilibrium market prices. (See Stiglitz 1974.) Thus Jack Hirshleifer's classic analysis is not that of a competitive stock market with rational consumers. If his analysis refers to a market in which there is a monopolist in information, his results require irrationality on the part of other consumers in the market. If his analysis refers to a market in which the market for information-acquisition is competitive, then the results discussed in the text apply.

[10] This is a consequence of the unavailability of endowment insurance. This result has some important implications for a question which until now has not been satisfactorily resolved: Can there be destabilizing speculation? In this context, we interpret that to mean: Can the attempt to engage in intertemporal arbitrage lead to higher price variability which is associated with lower utility? The answer is yes, and indeed such attempts at intertemporal arbitrage can lower welfare. This occurs, in our constant absolute risk aversion example, because by the portfolio separation theorem, information has no allocative role.

information acquisition, e.g., a comparison between the decentralized process of the capital market and a centralized process. This, in some sense, was the central question of the Lange-Lerner-Taylor-Hayek debate.

Although this earlier debate was presumably about the informational efficiency of alternative organizational structures, models in which the systems had to adjust to new information were not formulated; rather it was argued that if the information were to be the same, the allocation would be the same, and thus, a comparison of alternative organizations came down to issues like a comparison of cost differentials arising from different patterns of information flows, or different speeds of convergence. Our analysis has suggested that a decentralized economy is likely to be characterized by individuals having *differential* information, that the separation in the earlier discussion of information and allocative questions is inappropriate, and that alternative informational structures will be characterized by different real allocations. In particular, Grossman (1975b) formalized Hayek's contention that prices are aggregators of information. There it was proved that if prices are sufficient statistics, the competitive economy where traders have diverse information generates allocations that cannot be improved upon by a central planner with all the information. However such markets do not provide incentives for information acquisition for the reasons given earlier. Thus only markets with noise will exist in equilibrium and these markets will not produce prices which are perfect aggregators. In this case a central planner with all the information can improve on the competitive equilibrium. Thus in our view the Lange-Lerner-Taylor-Hayek debate comes down to the fundamental distinction between economies where: (1) prices and hence allocations are the outcome of a competitive arbitrage process which will, of necessity, be imperfect because of the costs of arbitrage as discussed in this paper, and (2) economies where prices and hence allocations are the outcome of a centralized allocative mechanism which will, of necessity, be imperfect because of the costs of monitoring bureaucrats.

Thus, although we cannot provide an answer to whether a centralized or decentralized organization is more efficient, without more knowledge of the costs of operating a centralized informational mechanism, what we have established is that the conventional formulations of this question are misleading if not incorrect.

# Information, Screening and Human Capital

By John G. Riley*

Given the large and growing body of research into the nature and extent of human investment decisions, it is somewhat surprising that until the recent work of Michael Spence and Joseph Stiglitz there has been little discussion of the information transmission process. Certainly in all the theoretical modeling of human capital accumulation it has been implicitly assumed that throughout the life cycle employers are aware of each individual's marginal value product.[1] That is, "traditional" human capital theory has included the assumption that information costs are negligible.

However, it is by no means clear that a firm can evaluate cheaply the productivity of an individual worker, especially when the nature of the job is nonspecific (e.g., the management trainee). Plausibly information about an individual's value often unfolds only slowly with time on the job. Plausibly also, the costs associated with placing an individual in a job for which he is ill-suited are far from negligible. If so, firms have a strong incentive to offer salary contracts in which earnings are contingent upon long-run performance.

But such offers will only be completely successful in screening out the less productive if job seekers are either risk neutral, or have very tight prior probabilistic beliefs about their own lifetime productivity levels. Since it seems reasonable to reject both assumptions, contingent contracting of this type seems likely to be severely restricted.

An extension of this argument, emphasized by Stiglitz, suggests that firms are unlikely to incur large expenditures for on-the-job evaluations of their employees' potential. First of all, risk aversion makes job seekers unwilling to bear these costs in the form of considerably lower initial salaries. Secondly, the possibility of raids by other firms makes each firm unwilling to itself bear the costs of identifying top talent.

The question then arises as to whether firms might exploit information about an individual's general educational achievements at school and college in attempting to predict productivity on the job. Taking this to the extreme, might firms make initial job offers based entirely upon educational credentials which on average succeed in attracting workers of the desired productivity level?

The key element in answering this question is the manner in which marginal costs of education vary across individuals. With everyone staying in school until the marginal increase in earnings resulting from additional education is just offset by marginal costs, those whose costs are lower will plan to accumulate higher credentials. Then if the marginal cost of an additional unit of education is highly negatively correlated with productivity on the job, it will be the more skilled individuals who accumulate more education.

But it is surely reasonable to argue that the more productive workers are also, on average, the faster learners hence those with lower opportunity costs. Intuitively then, it seems quite possible that educational screening by firms might result in

* University of California, Los Angeles. The helpful comments of Sherwin Rosen, Michael Darby, Dennis de Tray, Jack Marshall and Finis Welch are gratefully acknowledged.

[1] For a brief summary of recent theoretical and empirical advances, see F. Welch.

a self-selection process through which individuals of differing talents are effectively separated. That is, although productivity is not directly observed until later in the career, educational achievement might "signal" information about this productivity to potential employees.

In the following section a model of human capital accumulation is developed which attempts to capture the essence of the above discussion as simply as possible, while retaining the basic structure of traditional human capital models. It is argued that despite the nonexistence of a Nash equilibrium there exists a unique set of wage offers which satisfies an appropriately weaker equilibrium concept. The section concludes with a very specific formulation of the model which highlights the problems of testing the educational screening hypothesis using the traditional earnings function approach. For this special model, a measure of the costs associated with screening is also derived.

## I. A Human Capital Model with Educational Screening

Consider a population of individuals differing in an innate unobservable characteristic $n$ which is distributed continuously over $[n_l, n_h]$. An individual of type $n$ can attain a level of education $z$ by staying in school for the first t years of his life.

$$\text{(1)} \qquad \mathrm{t} = \mathrm{t}(n, z) \qquad \mathrm{t}_n < 0, \ \mathrm{t}_z > 0$$

The variable $z$, observed by potential employers, is assumed to summarize an individual's educational achievements; classes taken, grade average, quality of schools attended and so on. The signs of the partial derivatives indicate that a higher $z$ represents greater educational achievement, and that an individual with higher $n$ is a faster learner. An additional restriction that we shall impose is $\mathrm{t}_{nz}<0$, that is, the time needed to achieve a marginal increase in education is everywhere lower for those with higher values of $n$.

While we shall treat $z$ as a continuous variable it is assumed that there are discontinuities in the underlying production of education. For instance, it seems reasonable to argue that as a first approximation an individual has a choice of colleges which are distributed continuously. However, having made a choice it then takes a discrete interval of time for the individual to obtain the desired credential. It is therefore difficult for a firm to obtain enough observations of t and $z$ to be able to infer an individual's value of $n$ prior to school completion.

Suppose further that the market value $M$, of individual productivity discounted to the time of entry into the work force t, depends both on the unobservable characteristic $n$ and upon education achieved prior to entering the labor market.[2]

$$\text{(2)} \qquad M = M(n, z) \qquad M_n, M_z \geq 0$$

We begin by considering a simplified "traditional" human capital model in which marginal productivity is costlessly observed. Assuming that the nontime costs of education are $c'$ per year, an individual staying in school for t years has a present value of lifetime income

$$P(n, z) = e^{-r\mathrm{t}}M(n, z) - \int_0^{\mathrm{t}} e^{-r\tau}c'\,d\tau$$
$$= e^{-r\mathrm{t}}\{M(n, z) + c\} - c$$
$$\text{where } c = \frac{c'}{r}$$

Since $P(n, z)$ is maximized if and only if the logarithm of $P(n, z)+c$ is maximized, the optimal education for type $n$ is the solution of

[2] It is simplest to think of $M$ as the discounted value of an individual's marginal productivity over all points in the life cycle, where the profile of the latter, for any given levels of $n$ and $z$ is determined exogenously. However, $M$ may also be interpreted as the solution of an on-the-job human capital optimization problem.

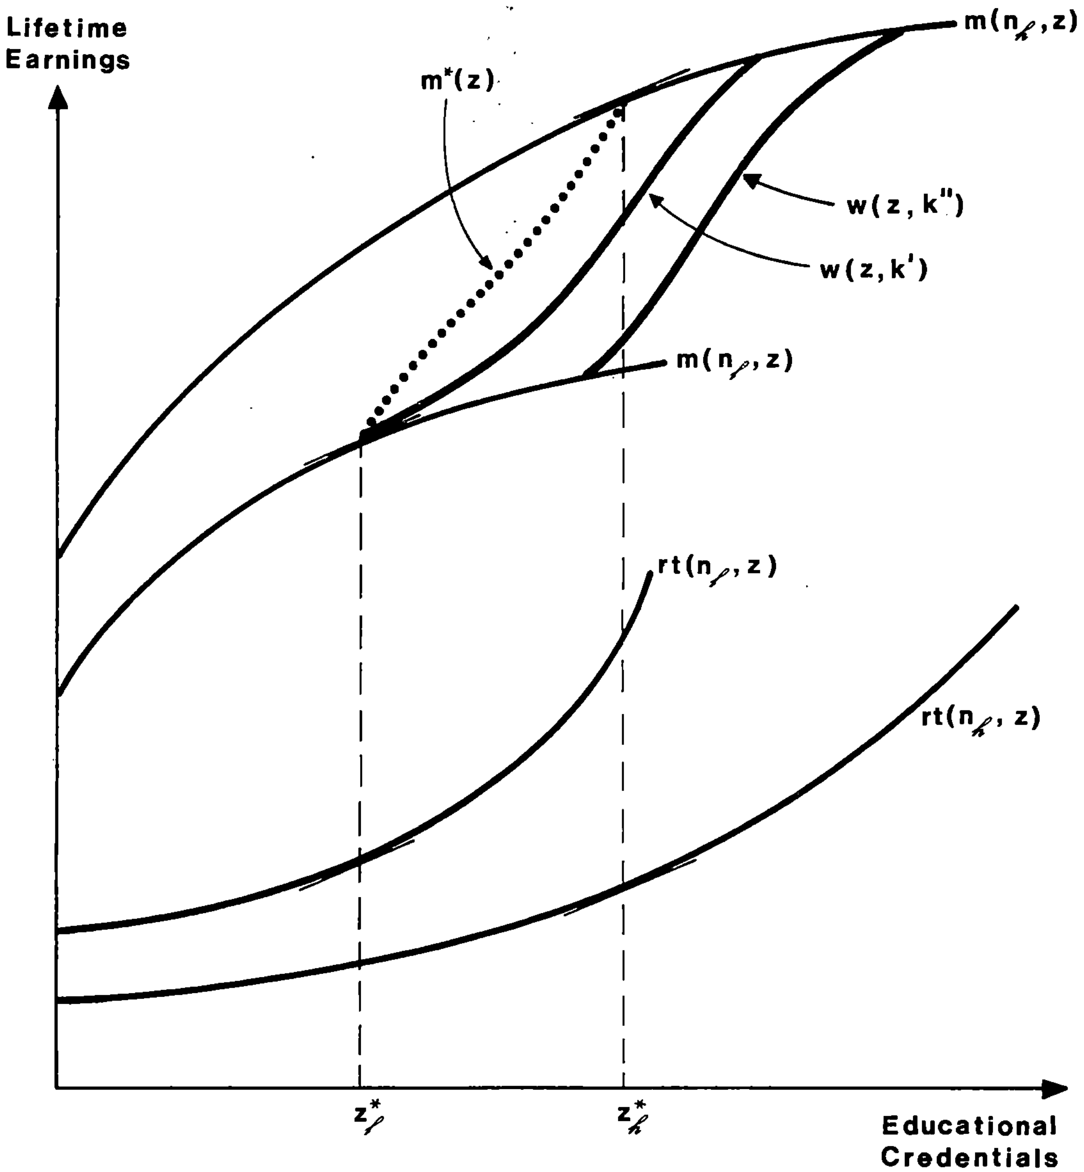

FIGURE 1: EARNINGS FUNCTIONS

$$\max_{z} \{m(n, z) - rt(n, z)\} \tag{3}$$

$$\text{where } m(n, z) = \log_e (M(n, z) + c)$$

The solution is depicted in Figure 1 for individuals at the extremes of the distribution of $n$. The curve $m^*(z)$ is the market equilibrium relationship between earnings and education. Making the reasonable assumption that the percentage increase in productivity associated with an additional unit of education is greater for those with higher $n$ (implying $m_{nz}>0$), it can be readily shown that optimal education $z^*(n)$ is strictly increasing in $n$.

We now consider the screenist view that productivity on the job is very costly to measure, at least in the early years. Sup-

pose each individual were to be offered discounted earnings $W(z)$ based on his educational achievements summarized here by $z$. Writing $w(z)=log_e(W(z)+c)$ and arguing exactly as above, the optimal choice of type $n$ is the solution of

$$\text{(3')} \qquad \operatorname*{Max}_z \{w(z) - rt(n, z)\}$$

Differentiating (3)′ twice yields the necessary conditions

$$\text{(4)} \qquad w'(z) - rt_z = 0 \qquad z > 0$$

$$\text{(5)} \qquad w''(z) - rt_{zz} \leq 0$$

Furthermore, differentiating (4) with respect to $n$ yields

$$(w''(z) - rt_{zz})\frac{dz^s}{dn} - rt_{nz} = 0$$

By assumption $t_{nz}$ is negative hence

$$\frac{dz^s}{dn} > 0,$$

that is, *those more favorably endowed with the unobservable $n$ attain higher educational credentials.*

Of course (4) and (5) are not sufficient for an equilibrium. What is required in addition is that employers' predictions about productivity levels should eventually be confirmed. Then given competitive behavior by firms, a further condition for equilibrium is that the gross earnings of those choosing an educational level $\hat{z}$ must equal their marginal value product.

$$\text{(6)} \qquad W(z) = M(n, z)$$

or, equivalently

$$\text{(6')} \qquad w(z) = m(n, z).$$

Given our assumptions about the functional forms one can in principle eliminate $n$ from (4) and (6′) and thereby obtain a first order differential equation, $w'(z)=f(w, z)$. Since solving such an equation yields an undetermined constant of integration, there are a whole family of earnings profiles $w(z, k)$, satisfying the following Spencian equilibrium conditions.

N–1. Individuals choose that education which maximizes discounted earnings.

N–2. The earnings of individuals achieving a given level of education equals (the average of) their marginal value products.

Two such profiles are depicted in Figure 1. It is easy to check that individuals accumulate more education if costs of observation result in its use as a screen. Differentiating (6′) totally with respect to $n$ yields

$$[w'(z) - m_z(n, z)]\frac{dz^s}{dn} = m_n.$$

Since we have already shown that

$$\frac{dz^s}{dn} > 0,$$

we have

$$\begin{aligned}\text{(7)} \quad m_z(n, z^s(n)) - t_z(n, z^s(n)) &\\ \leq w'(z^s(n)) - rt(n, z^s(n)) &\\ = 0 \qquad \text{from (4).}&\end{aligned}$$

But if $m$ were costlessly observable individuals would choose $z$ in order to make the left-hand side of (7) equal to zero. Then $z^*(n) \leq z^s(n)$ as depicted.

Spence's initial interpretation of these results was that an economy might settle in any of the states characterized by the arbitrary constant of integration $k$. In his terminology the conditions N–1 and N–2 yielded a *family* of potential "signalling" or "informational" equilibria. However the options open to firms were never adequately explored. It has since been shown by the writer that with simple extrapolative experimentation, all but one of the equilibria begin to unravel. The one profile that survives such experimentation, $w(z, k')$, has the property that those most disadvantaged ($n=n_l$) receive exactly the same earnings as they would if the productivity could be costlessly observed.

There is an appealing intuitive argument as to why this should be the case. In contrast with those elsewhere in the distribution, those on the "bottom rung" have no one lower down the ladder from whom they must be distinguished in order to earn a higher income.

The question as to whether this remaining earnings profile is an equilibrium is however a delicate one. As Rothschild and Stiglitz have indicated, there are circumstances in which there exists *no* set of contracts [in our case an earnings profile $w(z)$] satisfying N–1, N–2 and the following requirement for a Nash equilibrium.

N–3. Every alternative contract (that is, an earnings offer based on educational credentials) that might be offered by a single firm is nonprofitable.

Since it can be shown that for the model derived above, $w(z, k')$ does not satisfy N–3, it is perhaps tempting to reject this screening model on theoretical grounds.

However, N–3 seems unnecessarily strong since any firm exploiting it must also fear the reaction of other firms. This idea is formalized in the following weaker "reactive equilibrium" condition.

N–3′. For every alternative contract which is profitable if offered by a single firm, there is a second contract which yields profits to a responding firm and losses to the first firm.

It should be noted that arbitrary threats are excluded by the requirement that the revised contracts of a second firm must yield profits to that firm. This seems an appropriate restriction in the context of large numbers of competing firms.

Given that in the skilled labor market individuals are very often implicitly signing long-term contracts, it is valuable for each firm to develop a reputation about its salary structure, the opportunities for on-the-job training, etc. It therefore seems unlikely that any one firm could make a "quick killing" by switching to an alternative offer that yielded only short-run gains. Then at least for our application of the screening model N–3′ seems sufficiently strong to imply stability. Since $w(z, k')$ can be shown to be the unique profile satisfying N–1, N–2, and N–3′, it seems reasonable to describe this as the competitive screening equilibrium.

At this point it should be noted that considerable weight has been placed on the idea that productivity is a function of educational achievement, $z$, and that employers observe $z$. However, because of data limitations, most empirical studies have focused upon the return to years of education t.

While for the competitive screening equilibrium it is not necessarily true that years of education are an increasing function of $n$, we shall see for a specific example that this is indeed the case. Suppose $\mathrm{t}(n, z)=n^{-\alpha}z^{\beta}$ and $M(n, z)=nz^{\gamma}-c$. Then combining the necessary conditions (3′) and (6′) it can be shown that the equilibrium earnings profile has the following form

$$(W+c)^{\alpha}=k'+\frac{r\beta\alpha}{\beta+\alpha\gamma}z^{\beta+\alpha\gamma}$$

where $k'$ is determined by the requirement that those at the bottom of the distribution are exactly as well off as if $m$ were freely observable.

Eliminating $z$ and taking logarithms then yields

$$\begin{aligned} w &= log_e (W+c) \\ &= \alpha^{-1} log_e k' - \alpha^{-1} log_e \left(1-\frac{r\beta\alpha}{\beta+\alpha\gamma}\mathrm{t}\right) \\ &\approx A + Br\mathrm{t}; \qquad B>1 \end{aligned}$$

Of course this is precisely the Mincerian "earnings function" of traditional human capital theory. Since $B$ exceeds unity for all values of the parameters, our screening model also predicts a "rate of return" to

years of schooling in excess of the rate of interest. Clearly then, estimation of a single log earnings function will not yield inferences about the importance of educational screening.

We conclude this section by asking how costly is the screening mechanism as a method of predicting productivity differences. All that can be said for the general case is that everyone except the most disadvantaged ($n=n_t$) spend more time in school than he or she would if productivity were costlessly observable. Using the specific functional forms introduced above we can go further and ask just how much worse off individuals are in the screening equilibrium.

For simplicity we consider only the case in which nontime costs of education are negligible ($c=0$). Then in a world in which productivity could be costlessly observed, each individual would choose an education level and number of years in school to maximize $e^{-rt}nz^{\gamma}$, where $t=n^{-\alpha}z^{\beta}$. It is easy to check that for this special case every individual would choose the same number of years of schooling $t^*=(\gamma/r\beta)$.

Then writing the discounted earnings in the free information world as $V^*$ and the discounted earnings in the screening world as $V^s$ we have:

$$V^*/V^s = e^{-rt^*}m(n, z^*)/e^{-rt^s}m(n, z^s).$$

Substituting for $z$ using the special functional forms yields:

$$V^*/V^s = e^{r(t^s-t^*)}(t^s/t^*)^{-rt^*}. \tag{8}$$

Since in the screening equilibrium those at the bottom of the distribution are no worse off, we have $t^s(n_t)=t^*$. The "cost" of educational screening can then be calculated under different assumptions about the lower bound of the screened distribution. Assuming that only those going to college are screened ($t^*=12$), the cost of screening is hardly insignificant. With an interest rate of 6 percent the ratio $V^*/V^s$ climbs to 1.03 for those completing four years of college. After six years the ratio rises to 1.07.

Of course any implications drawn from one simple model must remain highly speculative. However it seems fair to conclude that the screening process described above is a rather costly method of differentiating highly productive workers from the rest of the pack.

## II. Concluding Remarks

The primary goal of this paper has been to link up the recent theoretical modeling of information[6] transmission via self-selection, with the traditional human capital literature. In examining a simple model of human capital accumulation we have suggested that there exists an appropriate definition of a competitive equilibrium in which individuals are hired on the basis of their credentials and are paid wages equal to actual productivity.

While the focus has been on the educational development of individuals prior to their accepting employment, it should not be inferred that on-the-job training is to be regarded as secondary. The screenist position is that education both enhances individuals' productivity levels and provides a mechanism for sorting out differences in these levels. Then one of the crucial roles of educational prescreening is to allow employers to select the more talented for jobs which involve considerable on-the-job training. Unfortunately this has not been recognized in several recent empirical studies which attempt to shed light on the educational screening hypothesis. As a result their conclusions should be regarded with considerable caution.[3] Indeed given that the Mincerian semi-log earnings function is derivable

[3] A major problem with these papers is that the "tests" are in the main not derived from an explicit model of the screening process. Where such modelling is implicit, it invariably involves a highly simplistic interpretation of the screenist position.

from a screening model, it might be tempting to infer that the educational screening hypothesis is not testable.

However, to take such a position it must be argued that direct monitoring of job performance is very costly in all skilled occupations. Surely it is more plausible that screening, if important at all, will be much more so for some classes of jobs than for others. Elsewhere in Riley (1976), it is shown that theory does yield predictions about differences between earnings functions for a class of jobs in which screening is used, and for a class in which productivity is cheaply monitored. These predictions are shown to be consistent with an empirical investigation by Kenneth Wolpin. While the latter draws a negative conclusion, it is argued that his results are more appropriately reinterpreted as providing mild support for the educational screening hypothesis. However, stronger conclusions must await a more systematic examination of the evidence. Hopefully future empirical work will reflect a clearer understanding of the potential dual role of education as both a mechanism for transmitting information about job applicants and for increasing productivity.

# Price Signaling in Experimental Oligopoly

*By* AUSTIN C. HOGGATT, JAMES W. FRIEDMAN AND SHLOMO GILL*

## I. Introduction

We report here a few results of oligopoly experiments which we carried out several years ago. These are laboratory experiments with human subjects along the lines of Lawrence Fouraker and Sidney Siegel (1963), Friedman (1967) and Hoggatt (1969). We sought to observe the predictive power of various theoretical equilibria. Then, to the extent that theoretical equilibria do not predict observed behavior, we seek to understand that behavior as best we can in the hope that the existing body of theoretical knowledge can be improved upon.

We used a simple textbook model of an oligopoly, then arranged for undergraduate student subjects to be the "firms" in the market. Our markets have 2, 3, 4 or 6 firms, each represented by one subject. One single "game" consists of a period of 1½ to 2 hours during which one group of subjects forms a market. For example, in a 3-firm market there would be 3 subjects each in a different room in the laboratory. Each would make the price and output decisions for his firm, and the pay to each for his participation in the game would consist only of the profits of his firm. At the beginning of the game, each would make the price and output decisions for his firm, and the pay to each for his participation in the game would consist only of the profits of his firm. At the beginning of the game, each subject would make his initial price and output decision. These initial decisions would remain in effect until changed by a subject; and he would be free to change either his price or output (or both) at any time. A particular game or market with its fixed set of firms (subjects) would remain in continuous operation for approximately an hour and a half.

The time periods are approximately 40 seconds each; and every fourth period, the subject receives a report on his sales, production, inventory, profit, etc. These time periods are sufficiently short that they approximate continuous time for the subject, especially given that there is not time in the whole game, except the beginning, when the subject *must* actively choose a price and an output level. Anytime afterward he can change his price and/or output level by entering new ones. They take effect at the start of the time period following.

Our experimental design was chosen with several objectives in mind: casual evidence, formal evidence (Friedman 1967), and intuition all suggest that sub-

A manual describing the experimental control programs and the observations on which this paper is based is available on request.

jects with no prior experience in the experimental setting will behave differently than they will after getting experience. We opted for experienced subjects; hence, we provided the experience. Further, we wanted reliable subjects who would come to the laboratory when they were signed up and we wanted the experiment to be a relatively large part of the subjects' activities over the days it was in progress. Meeting these objectives required: (1) recruiting a very large number of subjects who played several (three) games each which were preliminary to the main experiments. These games allowed a chance for subjects to drop out before doing so caused us problems, and also gave the subjects the necessary prior experience; (2) choosing from the subjects who remained through the three preliminary games three groups of 9 each who would be in three separate experiments. Each group of 9 had to have large blocks of available time in common so that the 8 games of each experiment could take place within a few weeks. These 8 games consisted of 2, 3, 4 and 6 firm symmetric (i.e., same cost functions for each firm) and asymmetric games.

The three groups of 9 subjects played under differing information conditions. The first (A group) had "complete information" and "forecasting." By complete information we mean that each subject knew the demand and cost parameters for all firms in his market. Under "incomplete information" he would know only his own. By forecasting is meant a sequence of time periods before the game begins during which the subjects make choices, as usual, but the periods are for practice. They do not gain or lose money. This was done by Fouraker and Siegel (1963) in some of their experiments. The other two groups operated with incomplete information with forecasting (B group) and complete information without forecasting (C group).

A final design characteristic of great importance is that the games are noncooperative and the players were unable to communicate with one another by means of written messages, oral conversation, etc. By "noncooperative games" we mean that the subjects could not make enforceable agreements.

## II. A Summary of Some of the Results

Signals are special price choices which are chosen to substitute for verbal communication when the latter is impossible. All price choices could be defined to be communication, but it may not be fruitful to do so. Most price choices are likely to be routine and dictated by simple and straightforward (relatively short run) profit considerations. Furthermore, the routine nature of most price choices is likely to make them pass without much notice. A very unusual price choice, by contrast, is likely to stand out and to cause other players to wonder and to seek specific explanations. One explanation is that the chooser of the unusual price is trying to say something to the others through his action. Given the shortness of the time periods, it is possible to suffer a low rate of profit for a short time to deliver a message and yet not bear much cost.

We have tried to look at signals in the overall context of price policy. In this section, some of our results on price policy, including those related to signals, are sketched. Production policy is left out of account because it appears to have no significant influence on price policy.[1]

To get a complete picture of price behavior, several separate pieces of analysis must be put together. The first is whether to increase price, leave it unchanged or decrease it. We estimate probabilities for

[1] In our report, we go into production policy in detail.

each of these as a function of variables of interest. Second, if price is changed, is the change to be a signal? Finally, if a routine price change is to be made, what should be the magnitude? These topics are taken up below.

### A. The Definition and Identification of a Signal

We recognize two distinct types of "unusual" price choice in the data. The first is a price change of unusually large magnitude. We call these "steps," and they may be of either sign. Their identification is deferred for a moment. The second is a sequence of two or three successive price changes which sum to zero. The simplest example is an increase in price of $dp$, followed in the next period by a decrease of the same magnitude. We have named these "pulses." Pulses are designated with the sign of the first price movement, making the pulse in the example positive. The crucial element of the pulse is that within three periods, price has returned to where it began. Pulses may be unambiguously recognized from the definition given above; however, steps cannot because no criterion has been introduced to separate them from more ordinary price changes.

We obtain a sample of observations on price changes and other variables by first deleting all periods in which price change is zero. Second, we delete all periods which are the first of the game because these may be shown to come from a different population. Third, we delete all observations which are part of pulses. The remaining observations are divided into two subsamples, one for price increases, the other for decreases. For each of the 8 types of game, using ordinary least squares we regressed positive price changes on the following variables: (1) a forecasting dummy ($F=0$ for games having forecasting); (2) an information dummy ($C=0$ for complete information); (3) time (t = the index of the period, counting only those the player has been in whose price change is the dependent variable in the observation); (4) the lagged price of the player whose price change is the dependent variable of the current observation ($Plg$); (5) the difference betwen $Plg$ and the contemporaneous mean of the prices of the other players in the game ($Plg-\overline{P}$); (6) $\Delta Plg$ (the most recent nonzero changes in $Plg$); and (7) $\Delta\overline{P}$ (the most recent nonzero changes in $\overline{P}$). All results reported in this paper are for the two-firm symmetric game.

We used these regressions to define steps. A step is any price change which lies at least two standard deviations away from the regression line. We removed all steps from the samples and reran the regressions. These regressions are intended to explain price choice when price is changed in a routine way. The price change regressions give the following equations:[2]

$$\text{(5)}\quad \Delta P = .024 + .035^{3}F + .032C + .00022t - .179^{3}Plg - .503^{3}(Plg - \overline{P}) + .088^{3}\Delta Plg - .042\Delta\overline{P}$$

for decreases and

$$\text{(6)}\quad \Delta P = .161 - .0115F - .069^{3}C - .000094t - .072^{3}Plg - .319^{3}(Plg - \overline{P}) - .0022\Delta Plg - .022\Delta\overline{P}$$

for increases. The equations may be thought of as conditional reaction functions, conditional on the direction of price movement.

Returning to the identification of signals, we used two criteria to define signals. A signal should be a particular con-

[2] These regressions also had one dummy variable for each subject. These are not shown here. Equations (5) and (6) show intercept terms for one particular subject.

[3] These coefficients are significant at the 5 percent level.

TABLE 1

| | | $P-\overline{P}$ | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | −.25 | | | 0 | | | .25 | | |
| | .25 | .589 | .380 | .031 | .550 | .254 | .196 | .510 | .059 | .430 |
| $P$ | .50 | .635 | .341 | .025 | .597 | .239 | .164 | .559 | .059 | .382 |
| | 1.00 | .719 | .265 | .015 | .686 | .203 | .111 | .651 | .057 | .292 |

spicuous action which has almost no *direct* effect on the firm's profit for the game. Pulses meet these conditions because they are conspicuous and, by returning quickly to the original price, they cause little change in profits (directly). Steps, though conspicuous, appear to violate the second condition because they seem to make a long-term shift in the level of a firm's price.

### B. Price Change vs. No Price Change

To estimate the probability of price change, we used logit analysis.[4] This analysis takes into account the presence of pulses in the data. For an observation, $P_+$ is a dummy variable whose value is 1 if a rival firm has finished a pulse in one of the three immediately preceding periods. $P_+=0$ otherwise. $P_-$ is analogously defined for negative pulses. Letting

$$(7)\quad a = .236 - .324F - .197C - .0012t - .777^5 Plg + .634(Plg - \overline{P}) - .638^5 P_+ + .161P_-$$

the estimated probability of no change in price is $1/(1+e^a)$ for the two person symmetric game. Again using logit, with

$$(8)\quad b = .160 + .312F + .371C - .00006t + .457Plg - 8.973^5(Plg - \overline{P}) - 1.701P_+ + .533P_-$$

the estimated probability of a price increase, conditional on price change taking place, is $e^b/(1+e^b)$.

[4] See David Brownston et al. (1975) and Daniel McFadden (1974).

[5] Coefficients divided by their standard errors exceed 2.

To give an idea of what probabilities emerge, Table 1 shows the probability of no price change, price increase and price decrease for various values of $Plg$ and $Plg-\overline{P}$ with $t=200$, $F=0$, $C=0$, $P_+=0$ and $P_-=0$. The single period Cournot equilibrium occurs at $Plg=.5$ and $Plg-\overline{P}=0$. For each column and row there are three entries. The first is the probability of no change, the second, of increase and the last, of decrease.

The lower is a firm's price, the higher the probability it will be increased; and the lower it is in relation to the other prices, the higher the probability of increasing it.

### C. The Probability of Signals

Again, using logit, we estimated the probability of emission of a signal. As these are rare events, we failed in attempts to relate emission to signals received. With

$$(9)\quad c = -2.825^5 - .191F + .029C - .002t - .648Plg + 1.133(Plg - \overline{P})$$

the probability of a signal is $e^c/(1+e^c)$. Letting

$$(10)\quad d = .422 - .686F - .211C + .0008t - .759Plg - 7.222^5(Plg - \overline{P})$$

the conditional probability of emission of a positive pulse, given that a pulse is emitted, is $e^d/(1+e^d)$. Probabilities for no signal, plus signal and negative signal are given in Table 2. In Tables 2 and 3 the labeling of rows and columns is identical to Table 1. Both negative and positive signals are

TABLE 2

| | | $P-\overline{P}$ | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | $-.25$ | | | 0 | | | .25 | | |
| | .25 | .975 | .022 | .002 | .967 | .019 | .013 | .957 | .008 | .034 |
| $P$ | .50 | .979 | .019 | .003 | .972 | .015 | .013 | .963 | .006 | .031 |
| | 1.00 | .985 | .013 | .003 | .980 | .009 | .011 | .973 | .003 | .024 |

more probable the lower is a firm's price. Plus signals are more probable as the firm's own price is lower in relation to the prices of the others, while the probability of negative signals rises as the firm's own price rises relative to the other's price.

### D. *Putting Pieces Together to Describe Expected Price Behavior*

The information collected may be thought of as a rather complicated reaction function. The regression equations for price increases and decreases are, by themselves, like ordinary reaction functions; however, they estimate price changes conditional upon change taking place. There is at any time a substantial probability that no change will occur. An equilibrium vector of prices in the present context is characterized by prices such that the expected price change is zero. This means that for each player the probability of price increase multiplied by the expected size of an increase (given that an increase will occur) plus the probability of decrease multiplied by the expected size of a decrease should be zero. For the two-person symmetric game, this occurs at a price of .826 if t is taken to be 200 and at .822 if t is 300. The Cournot equilibrium is at $P=.5$ and $P-\overline{P}=0$, while the joint profit maximum is at $P=1$ and $P-\overline{P}=0$. As signals occur rarely, they have small impact on equilibrium behavior. To examine their *local* impact we imagined, contrary to possibility, that signals could be sent in every period. This shifts the equilibrium above the joint maximum price for negative signalling and below the Cournot price for positive signalling. These are strong effects.

Table 3 shows the expected value of a price increase, given that increase will take place, the expected value of a decrease, given that a decrease occurs, and the expected value of price. For example, at the Cournot equilibrium ($p_i=.5$, $P_i-\overline{P}_i=0$), these are .125, $-.113$ and .011.

The prices at which expected price change is zero make sense in comparison with earlier experimental research. The general behavior described above is also plausible, though it differs in a conspicuous way from the theoretical literature on reaction functions. That literature sup-

TABLE 3

| | | $P-\overline{P}$ | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | $-.25$ | | | 0 | | | .25 | | |
| | .25 | .223 | .057[a] | .087 | .143 | $-.069$ | .023 | .063 | $-.194$ | $-.080$ |
| $P$ | .50 | .205 | .012[a] | .070 | .125 | $-.113$ | .011 | .045 | $-.239$ | $-.089$ |
| | 1.00 | .169 | $-.077$ | .044 | .089 | $-.203$ | $-.004$ | .009 | $-.329$ | $-.096$ |

[a] These values should, of course, be negative. They result from extrapolation beyond the main range of the data.

poses that as soon as a steady state pair of prices is reached, there is no further price change; and before such prices are reached, prices change in each period. Our subjects behave differently. The counterpart of the steady state is where expected price change is zero; however, we would not see zero change here. Meanwhile subjects do not act on price most of the time, so, even away from the "equilibrium" no price change is more probable than change. Furthermore, prices are not changed on a regular schedule. Whether these differences are important or only cause minor random deviations remains to be seen.

A difference of clear substance is the divergence between price increases and price decreases, and the presence of signals. The more formal reaction function literature formulates present price as a function of the past prices observed in the market. There is no asymmetry of behavior between increases and decreases. By contrast, our experimental evidence suggests that subjects make a three-way decision for routine price behavior where the alternatives are increase, decrease and no change. Each of the first two has its own rule (equation) to determine size. Superimposed on this is signaling where unusual price movements are made to apparently convey a message. We have not gotten much beyond identifying these. It would take further study and a very large sample to see their role clearly.

# An Experimental Market for Public Goods: The *PBS* Station Program Cooperative

*By* John A. Ferejohn and Roger G. Noll*

Beginning with the 1974–75 season, the Public Broadcasting Service (*PBS*) undertook a three-year experiment to decentralize through a market process the selection of programs to be broadcast over the national noncommercial television network. The experimental market, called the Station Program Cooperative (*SPC*), enables each of the approximately 150 participating stations to "vote with dollars" for the programs they prefer, based on information about the subject matter, quality and costs of the alternatives.

The *SPC* had two purposes. The first was to determine whether a decentralized market mechanism for acquiring national programming can be established that, first, has a reasonable cost and, second, retains the basic features of a network. A network is a means of centralizing the acquisition, transmission and promotion of programming. Although the advantages of networking are several, probably the most important is that it saves substantial transactions cost in comparison to the two other alternatives: syndication (in which each station negotiates for nationally distributed programs with the owner of the rights to the program) and localism (in which each station produces its own programming). (See Bruce Owen, Jack Beebe and Willard Manning.)

The second purpose of the *SPC* is to determine its impact upon the types of programs that are broadcast. Centralized programming authorities such as the present commercial networks and the Corporation for Public Broadcasting, because they are few in number, are relatively easy targets for political pressure with respect to program content, may at least tacitly collude in programming decisions, and in any event, have limited experience concerning the nature of the demand for programs in all markets in the network system. (See Noll, Merton Peck and John McGowan, Ch. 8.) Because of the cost advantages of networking and the technical barriers to entry of new networks, in principle a network can produce an inefficient programming mix and still meet minimum standards of profitability or, in the case of the noncommercial sector, public acceptability. Concomitantly, station managers may be too unsophisticated about judging programming quality and sensing the structure of demand in the local market to select programming that, in benefit-cost terms, is "better" than that selected by a centralized decision maker. While direct evidence on which system works better is not possible to acquire, two useful questions can be answered, at least in principle: (1) Do the *SPC* and centralized decision making lead to the selection of different programs, and if so, is that difference systemmatic? and (2) Which system produces higher audience

* California Institute of Technology. Financial support for preparing this paper was provided by the National Science Foundation RANN program, grant #APR76-01920. We are indebted to Richard Beatty and *PBS* for providing us with remarkably complete data for all three *SPCs*. We are, of course, solely responsible for the contents of this paper.

ratings and/or greater total revenues (private contributions plus government appropriations) for the noncommercial television network? This paper does not address these issues. (See Natan Katzman and Noll.) That research is still underway.

Though unintentional, the *SPC* experiment has a third, more general use. The *SPC* is a test of a novel mechanism for public decision making about a particular class of public goods, specifically those for which binary (all or nothing) exclusion is possible.

The purpose of this paper is to make the connection between the *SPC* and the theory of public goods, and to draw some preliminary conclusions about the workability of this kind of artificial market. It is, therefore, addressed to the first and third issues.

A television broadcast is a public good in that the cost of transmitting the program within a given geographical area is independent of the number of television sets that are tuned to it. So, too, is the program a public good as far as each station is concerned. Excluding rents arising from differing popularities of programs, the costs of a program are independent of the number of stations over which it is broadcast. Even national network distribution costs are, in most instances, independent of the number of stations receiving the program. Nearly all programs distributed by networks are carried over the national telecommunications system. If the program is distributed from coast to coast, the transmission costs are only slightly dependent on the number of intermediate points at which the program is received and broadcast. As the distribution of television programs moves to satellite transmission, national interconnection costs will become totally independent of the number of stations in the network.

Nevertheless, exclusion of stations from use of a particular program is also essentially costless. In both the commercial and noncommercial systems, few stations accept ("clear") all network programs. One way to view the process by which stations make programming decisions is that each station has a preference ordering over all available programming possibilities and selects the most preferred feasible set of programs, given its budget and the costs of the alternatives. Since programs are public goods, these decisions have external effects; namely, if a program is selected by one more station, costs per station decline, and hence from the vantage point of other stations some programming alternatives involving this program that dominate a previously selected alternative may become feasible.

## I. The Mechanics of the *SPC*

The heart of the *SPC* is a mechanism for calculating the price of each program for each station that broadcasts it. These prices are determined through a sequential process in which a series of trial price vectors are proposed, responded to, checked for acceptability with program producers, and, if they generate too little or too much revenue, updated.

The first stage of the *SPC* is the dissemination of program proposals. Program producers—primarily stations, but also some independents such as the Childrens Television Workshop ("Sesame Street")—provide descriptions of proposed programs (series or special events), prices, and in many cases pilots. The form of the final proposal is usually negotiated with *PBS*, which among other things, tries to keep program prices roughly in line with production costs. In each of the first three years of the *SPC*, about 250 programs were proposed.

The second stage of the *SPC* culls the list of proposed programs in the following manner. On the basis of the final pro-

posals, stations are asked to assign "priorities" to each program, which amounts to rating the programs on a scale of one to five (five is best). The sum of the ratings for each program is calculated, and the programs are rank-ordered according to their scores. Programs ranking in the top third, plus a few others which *PBS* believes deserve special consideration (their classifications show high variance, or additional information about the program will become available and might change scores), are then allowed to enter the market phase of the selection process. This process served to cull the list of contenders to 93 in the first year (*SPC* I), and 136 in the second (*SPC* II).

Next, the market phase of the *SPC* is begun. Its main feature is an algorithm for calculating the program prices facing each station. The formula for calculating the price $P_{ij}$ of program $j$ to station $i$ is:

$$P_{ij} = C_j \left( .8 \frac{B_i}{\sum_{k \in Sj} B_k} + .2 \frac{N_i}{\sum_{k \in Sj} N_k} \right)$$

where

$C_j$ = the cost of program $j$
$B_k$ = the programming budget of station $k$
$N_k$ = the population of the area served by station $k$
$S_j$ = the set of indexes of stations that have agreed to purchase program $j$.

Obviously, prices and the identity of purchasing stations are interdependent. In the *SPC*, the initial price calculations are based upon the assumption that each program is selected by stations representing 80 percent of the combined budget and total audience of the entire public television system. In subsequent rounds, prices are calculated on the basis of the budgets and populations of the stations selecting the program in the previous round. Once the market has eliminated all but a few more programs than are likely to be purchased, the *SPC* manager announces that in subsequent rounds stations will be required to continue selecting a program that they selected in the previous round if the price does not increase. The market process continues until all programs either generate revenues acceptable to the producer of the program, receive no votes from other than the producing stations at prices based upon selections made in the previous round, or are withdrawn from consideration by the producer.[1] Then a final "late purchase" round takes place in which each station can select additional programs from the list of purchased programs. Stations eventually purchased 25 programs in *SPC* I and 38 in *SPC* II, each station buying about 20 in the first and 30 in the second.

The costs of programs are only upper bounds on the amount of revenue producers eventually receive from the *SPC*. At any phase of the market process, a producer may guarantee that the current price vector for his program will not rise —that is, that the producer will absorb the shortfall in revenues in relation to the listed total cost. Since many of the programs entered in the *SPC* will be produced in any event for local or regional audiences, any revenue the producer receives from the national market is a net gain. Similarly, coalitions of buyers are permitted to guarantee the stability of current prices by agreeing to make up the difference between revenues and costs.

## II. The Economics of the *SPC*

The appropriate theoretical framework for analyzing the properties of the *SPC* is the extension of general equilibrium

[1] The purchase rounds are conducted through a nationwide computer network. Each station manager sits at his teletypewriter, receives messages about the progress of the *SPC* (including price updates), and each round enters his selections.

theory that includes pricing of public goods. Models of optimal choice of political jurisdiction, the theory of clubs without congestion, and Lindahl pricing of public goods are obvious examples. (See James Buchanan, Bryan Ellickson, Duncan Foley, Eric Lindahl, R. W. Rosenthal and Paul A. Samuelson). In a market with $p$ programs, a particular pattern of program selection and rejection can be represented by a $p$-dimensional vector in which the elements are either zero or one according to whether a program was rejected or selected by the station. A family of $2^p$ such vectors describes all possible decisions by a station, and presumably a station is able to generate a transitive weak ordering over these vectors that reflects its programming preferences. The problem faced by a station is to pick the highest-ranking selection vector—e.g., a vertex on the $n$-dimensional unit square—that is feasible, given its budget and the prices of the programs.

Each program producer seeks to maximize the revenue it derives from a program, subject to two constraints: the revenue received through the *SPC* must cover the incremental cost of allowing the program to become national, and it must not exceed the maximum allowable costs negotiated with *PBS*, which are intended to be approximately total production costs. The minimum and maximum prices are identical for programs that will be produced only for national distribution unless the producer can find other sources of financial support, is willing to take a loss, or is a station that values the program idea sufficiently highly that it is willing to pay more than its share of the costs to guarantee its production.

The *SPC* is a process of generating for each station a price vector and a vector of selections and for programs a cost vector that constitute a stable equilibrium in the feasible production and budget sets. This algorithm has two features: an initialization procedure that generates the first trial set of prices and an updating procedure that changes prices until a stable equilibrium is found.

From a theoretical standpoint, it is a miracle that the process works. One source of difficulty is that the production set is not convex. The space in which programs are located is of an unknown number of dimensions of program characteristics. Past research has been notably unsuccessful in defining these dimensions in an empirically useful way (see Edward Greenberg and Harold Barnett), but as a working hypothesis a program can be thought of as a particular combination of production talents, production quality (e.g., the average number of "takes" per printed scene, the number of scenes filmed on location, etc.), and subject matter. Each program proposal in the *SPC* is, to all practical purposes, a single point in this space—not a ray, but a point—because essentially no variance is possible during the operation of the *SPC* in any of the relevant dimensions, including the number of units of the program to be sold. As a result, linear combinations of programs cannot be formed to arrive at locations in program-characteristics space that are between the program points. Consequently, even if at all factor prices one unit of a particular program would never be selected in market competition with one unit of each of the other programs, it may still be selected in the *SPC* since the combinations of other programs that strictly Pareto dominate it cannot generally be formed.

The first two *SPCs* had another potential problem arising from the initialization procedure. Because the initial price vector was calculated from grossly unrealistic assumptions about the number of stations that would select each program, the station selection vectors they called forth were

necessarily outside the system's feasible set. In *SPC* I second round prices averaged nearly four times first-round prices! This kind of initialization causes a massive reduction in the number of program selections per station in the first few rounds. If initial selection vectors are sufficiently diverse that few programs appear clearly out of the running in the initial stages, stations will not quickly concentrate votes on a relatively few popular offerings, and so for nearly all programs prices will continue to rise through the first few rounds. If preferences are sufficiently diverse and the number of programs large enough compared to the number of stations, the process might not converge to the feasible set. One can imagine a desperate round in which each station, facing astronomical prices, picks exactly one program, all stations pick a different program and no program can cover costs on the budget of a single station.

Theoretically, whether initialization and updating procedures for the *SPC* can be derived that reach a stable equilibrium is as yet unanswered. Our conjecture is that they can, particularly if the procedures constitute an improvement algorithm rather than a search for the feasible set from outside it.

The third *SPC* will try a new initialization procedure. Instead of calling out a selection vector and observing a budget-breaking consequence, each station will provide the *SPC* with a total expenditure limit and a preference ordering of the programs. The *SPC* will then calculate new prices based on these preferences and tell each station how far down its preference ordering it can go, given its budget constraint. For the first round, preference ordering will not be based on an explicit price formula as stations will draw their own inferences from program cost information. In subsequent rounds, the same price updating procedure used in the other *SPCs* will be used. The basic idea is first to find a point on the boundary of the feasible set, and then move along the boundary until an equilibrium is reached. The main difficulty with the procedure is finding a nontrivial initial feasible solution.

### III. The Results of the First Two *SPCs*

The *SPC* results of interest here relate to the convergence properties of the system; we will not investigate the issues related to the types of programs the system selected.

In both of the first two *SPC* experiments, the market phase of the selection process was allowed to run for twelve rounds. *SPC* I had two-thirds as many programs from which to choose, and eventually purchased two-thirds as many programs, as *SPC* II.

By round 6 in *SPC* I and round 8 in *SPC* II, the programs that were purchased had all but been determined. In *SPC* I, the three programs still in the market during round 6 that were subsequently eliminated received support from 3, 5 and 8 stations, respectively, while the three lowest numbers of supporting stations for programs that were eventually purchased were 19, 21 and 34. Nineteen of the 25 programs that were eventually purchased were, by round 6, receiving support from over half of the stations (75).

In round 8 of *SPC* II, the six programs that were eventually dropped received support from 2, 9, 36, 40, 64 and 66 stations, respectively. Of the 38 programs that were eventually purchased, 31 were supported by more than half the stations in round 8. Five more received support from between 58 and 73 stations and two that were eventually purchased received only 40 and 42 votes in round 8. One of the latter was clearly a special case, consisting of 100 sixty-second messages promoting coming attractions. Thus, of

the ten conventional programs receiving support from between 36 and 73 stations, six were purchased. All six that were purchased had total costs below $15,000 per program-hour, which is inexpensive. Of the four that were rejected, hourly cost data are available only for two. One was a children's program that cost $57,000 per hour—more than triple the cost of "Sesame Street" or "The Electric Company"—and the other was a documentary series that cost more than $100,000 per hour. Thus, further classification of programs by cost apparently cleanly separates the purchased from the excluded programs.

In both markets, the first few rounds saw massive reductions in the number of programs selected per station and generally rising program prices. In *SPC* I, prices for programs remaining in the market rose abruptly at the start, and did not, on average, begin to fall until after the seventh round, while in *SPC* II, prices began to fall after round 3.[2] In both markets, the average price of purchased programs did not return to the average round 1 initialization price until the last round.

The first two *SPCs* appear to have reached an equilibrium, at least within the context of the operating rules. Although the twelve purchase rounds occurred over only a few days, late purchases were possible for several weeks. Two programs in *SPC* I and seven in *SPC* II increased the number of stations supporting them by 3 to 8 percent during the late purchases. In both markets about 55 percent of the programs made no additional sales during the late purchase, while 28 percent in *SPC* I and 26 percent in *SPC* II increased their number of supporters by less than 2 percent.

Outside the context of the *SPC* rules, the final list of programs purchased may not be an equilibrium. The key operating rule in the *SPC* appears to be the non-reincarnation rule: once eliminated, a program cannot reenter the market at a later stage. This eliminates the possibility of cyclic selections, but may also prevent the system from reaching an efficient equilibrium if one exists. About one-third of the programs that eventually were purchased received twice or more as many votes in the final selection round as they did at their ebb during the market. Many of these programs also had mediocre pre-market rating scores, averaging below a ranking of three in the five point scale.

With the exception of buyer and seller guarantees as explained above, stations did not have an opportunity to price-discriminate against themselves in order to register an intense preference for a particular program. A group of stations with an intense preference for a particular program, A, but unable to guarantee its purchase, could not offer remaining stations a discounted price to tempt them away from another program, B. If the remaining stations had only a slight preference for B over A, the pricing rule could prevent a substitution of A for B at prices that would make the move a Pareto improvement.

## IV. Conclusions

Because our research on the *SPC* has only begun, few conclusions can be drawn as yet. Most of the inferences we are prepared to draw relate to the additional research that is required to gain a better understanding of how the system operates, if it could be adapted to the acquisition of other public goods (national parks, commercial broadcasting, etc.), and whether it produces acceptable programming results at reasonable transactions cost.

[2] This statement is true for both the unweighted average price and the average of prices weighted by the number of stations selecting the associated program. Movements of the latter index the change in the average budget of a station, holding its selections at the mean of all stations.

An obvious candidate for further work is theoretical examination of the equilibrium properties of the *SPC*. Two types of questions are relevant: What normative properties, if any, do the existing *SPC* rules have, and would other initialization and updating procedures work better? Although of some interest is whether the system reaches an equilibrium that is Pareto optimal, for policy purposes the conclusion that it does not is not persuasive that the *SPC* should be abandoned. A centralized system, for reasons outlined briefly above, also is likely to be inefficient. Of prime practical interest are the consequences of alternative procedures for operating the system.

Laboratory experiments could provide a useful additional source of information about alternative structures of *SPC*. Very briefly, the idea of each experiment would be to ask a group of subjects to select an unstated number of items from a list of alternatives. Total costs for each alternative would be provided, as well as a payoff function for each group member. An initialization and updating procedure would be adopted, and the general mechanics of the *SPC* followed. By running the identical experiment several times, the uniqueness of the results of the system could be checked. By varying payoff functions while holding procedures fixed, the sensitivity of the system to intense preferences could be explored. And by varying procedures while holding payoffs constant, the performance of various initialization and updating methods—particularly of improvement algorithms and of other procedures—could be compared. The advantage of the experimental system, of course, is that it is far less expensive—in terms of operating costs, risks to something of significant value (the public television system), and the time between observations—than, through the years, manipulating the *SPC*.

Finally, the overriding conclusion of our investigations to date is that experimental markets for public goods are an interesting, potentially useful and almost completely unexplored focus for research. If this paper conveys to other social scientists our perception of the fascinating possibilities suggested by the *SPC*, its most important purpose will have been served.

# Experimental Economics: Induced Value Theory

By VERNON L. SMITH*

It is the premise of this paper that the study of the decision behavior of suitably motivated individuals and groups in laboratory or other socially isolated settings such as hospitals (R. Battalio, J. Kagel, et al., 1973) has important and significant application to the development and verification of theories of the economic system at large. There are two reasons for this.

1. The results of laboratory studies can serve as a rigorous empirical pretest of economic theory prior to the use of field data tests. The state of economic hypothesis testing, as it is sometimes done, can be described roughly as follows: based on casual observation of an economic process and the self-interest postulate, one develops a model, which is then tested with the only body of field data that exists. The results of the test turn out to be ambiguous or call for improvements, and one is tempted to now modify the model in ways suggested by the data "to improve the fit." Any test of significance now becomes hopelessly confused if one attempts to apply it to the same data. Where it is possible and feasible, as in the study of price formation, the data from controlled experiments can be used to test hypotheses stemming from prescientific casual observations of a particular phenomenon. The fact that one can always run a new experiment means that it is never tautological to modify the model in ways suggested by the results of the last experiment. Since economic theories always deal with certain alleged behavioral tendencies in isolation, the experimental laboratory is uniquely well suited for testing the validity of such theories. It provides an exceptionally rigorous discipline of our ability to model elementary situations whether or not field data can be regarded ultimately as having been generated by such elementary models.

2. The results of experiments can be directly relevant to the study and interpretation of field data. Other so-called nonexperimental sciences such as meteorology and astronomy have depended crucially for their development on (a) small-scale laboratory experiments in the physics of mass motion, thermodynamics, and nuclear reactions; and (b) the postulate that such microphysical experimental results apply, with suitable modifications, to the study of the weather, the planets and the stars. This parallelism, "As far as we can tell, the same physical laws prevail everywhere" (Harlow Shapley 1964, p. 43), also has application to the study of social economy. Laboratory experience suggests that all of the characteristics of "real world" behavior that we consider to be of primitive importance—such as self-interest motivation, interdependent tastes, risk aversion, subjective transactions cost (time is consumed), costly information (it takes time to acquire and process information), and so on—arise naturally, indeed inevitably, in experimental settings. Anyone who had begun the study of economics in

* Department of Economics, University of Arizona. Support from NSF grants is gratefully acknowledged. This paper is an articulation of concepts originally developed in the course of several seminars in experimental economics taught at Purdue University, 1964–67.

the laboratory without these concepts would soon find himself inventing them. Furthermore, the process of experimental design forces one to articulate rules and procedures, the collection of which forms an institution, organization, or "body of law" with striking "real world" parallels (cf. Martin Shubik 1974). The laboratory becomes a place where real people earn real money for making real decisions about abstract claims that are just as "real" as a share of General Motors.

## I. The Theory of Induced Valuation

Control is the essence of experimental methodology, and in experimental exchange studies it is important that one be able to state that, as between two experiments, individual values (e.g., demand or supply) either do or do not differ in a specified way. Such control can be achieved by using a reward structure to induce prescribed monetary value on actions. The concept of induced valuation (Smith 1973) depends upon the postulate of *nonsatiation:*

> Given a *costless* choice between two alternatives, identical except that the first yields more of the reward medium (usually currency) than the second, the first will always be chosen (preferred) over the second, by an *autonomous* individual, i.e., utility is a monotone increasing function of the monetary reward, $U(M)$, $U' > 0$. [pp. 22–23]

This postulate applies to experiments designed to test price theory propositions conditional upon known valuations. Separate experiments can be designed to test propositions in preference theory.

Example 1. In the experimental study of competitive equilibria in isolated markets it is necessary to induce known (to the experimenter) supply or demand on individual subjects. Let subject buyers $i=1, 2, \ldots, n$ each be given a table listing increasing concave total receipts $R_i(q_i)$ representing the currency redemption or "resale" value of $q_i$ units acquired by subject $i$ in an experimental market. The instructions state that if subject $i$ acquires $q_i$ units at prices $p_1^i, p_2^i, \ldots, p_{q_i}^i$, he will receive cash earnings of $R_i(q_i) - \sum_{k=1}^{q_i} p_k^i$. Neoclassical demand is defined as the quantity that would be purchased as a function of a given hypothetical price $p$. By this definition, if for a fixed $p$ a subject purchases $q_i$ units, he earns $R_i(q_i) - pq_i$. If his utility for money is $U_i(M_i)$ he will wish to $\max_{q_i} U_i[R_i(q_i) - pq_i]$. We have an interior maximum if and only if

$$(R_i' - p)U_i' = 0,\ U_i' > 0, \qquad \text{or } q_i = R_i'^{(-1)}(p),$$

for the class of functions $U_i$, $R_i$ such that $(R_i' - p)^2 U_i'' + U_i' R_i'' < 0$. This reward scheme induces arbitrary demand $R_i'^{(-1)}(p)$ on subject $i$, and the experimentally controlled market demand becomes $Q = \sum_{i=1}^{n} R_i'^{(-1)}(p)$ independent of the $U_i$.

Similarly, let $j=1, 2, \ldots, m$ subject sellers be given cost functions $C_j(q_j)$, and receive cash earnings $\sum_{k=1}^{q_j} p_k^j - C_j(q_j)$ from selling $q_j$ units at prices $p_1^j, p_2^j, \ldots, p_{q_j}^j$. If utility is $V_j(M_j)$, $V_j' > 0$, then $\max_{q_j} V_j[pq_j - C_j(q_j)]$ implies a supply function $q_j = C_j'^{(-1)}(p)$. The experimentally controlled market supply is $Q = \sum_{j=1}^{m} C_j'^{(-1)}(p)$ independent of the $V_j$. Such induced supply and demand become flows per period in experiments in which trading is conducted in a sequence of periods.

Example 2: Let subject traders be given a table listing increasing concave currency receipts $M(x_1, x_2)$ to be paid by the experimenter for terminal stocks $(x_1, x_2)$ of each of two abstract experimental commodities exchanged in an experimental general equilibrium market. Then subject $i$'s unknown utility for currency $U_i(M)$ induces the value $U_i[M(x_1, x_2)]$ on terminal stocks $(x_1, x_2)$. Consequently, the experimentally controlled indifference map given by the level contours of $M(x_1, x_2)$ are induced upon subject $i$ independent of his particular $U_i$. That is, each subject's marginal rate

of substitution of $x_2$ for $x_1$ is given by $U_i' M_1/U_i' M_2 = M_1/M_2$, $U_i' > 0$. This allows the "Edgeworth Box" representation of general exchange equilibrium to be reproduced experimentally by inducing a given indifference map on each member of one group of subjects, and another indifference map on each of a second group of subjects. With given endowments of the abstract commodities for members of each of the two trading groups, the experimental stage is set for exchange.

## II. Some Qualifications

There are three important qualifications to the nonsatiation postulate:

1. There may be subjective costs (or values) associated with market decisions. In a competitive market experiment a subject may find it arduous to monitor and make quotations, and to execute transactions. If such considerations are not negligible, then we lose some control over the process of induced valuation. The effect of boredom and the subjective costs of decision making have been emphasized in the important study by Sidney Siegel (1961). Roger Sherman (1974) has interpreted alleged violations of the Savage axioms in terms of the subjective cost of making the appropriate computations. In terms of the utility interpretation of the previous section, the utility function can now be written $U^i(M_i, E_i)$ where $E_i$ is the "transactional effort" required to obtain reward $M_i$ (cf. Harvey Leibenstein 1969; and implicitly, Ronald Coase 1960). To see the potential implications of costly choice, consider example 1 of the previous section in which demand $R_i'^{(-1)}(p)$ is induced upon $i$. Utility is now $U^i\{R_i[q_i(E_i)] - pq_i(E_i), E_i\}$ where it is assumed crudely that "bargaining effort," $E_i$, results in the purchase quantity $q_i(E_i)$. Then $\max_{E_i} U^i$ implies $(R_i' - p)\, q_i' U_1^i + U_2^i = 0$, and now the induced demand is $q_i = R_i'^{(-1)}(p - U_2^i/U_1^i q_i') < R_i'^{(-1)}(p)$, if $U_2^i < 0$, $q_i' > 0$. Hence, if there is a cost (value) to transacting in the experimental task, the induced demand will be smaller (larger).

There are several ways of dealing with this problem:

(a) One is to examine the experimental results to see if the quantity exchanged is less than predicted. If it is, this is consistent with a significant transactions cost. Awareness of such transactions cost may provide valuable clues to understanding why certain experiments may fail to produce predicted results. The process is not tautological as long as one can redesign the experiment and show that such conjectured transactional effects can be reduced.

(b) Another approach is to use a reward structure to compensate for, or offset, the subjective costs of transacting. There are two ways of doing this. (i) One way (Siegel 1961) is to simply raise the reward level. This increases the subjective value relative to the subjective cost of acquiring units $q_i$. Let $\alpha$ be a scale parameter determining reward level. Then utility becomes $U^i\{\alpha(R_i[q_i(E_i)] - pq_i(E_i)), E_i\}$. Induced demand is now $q_i = R_i'^{(-1)}(p - U_2^i/U_1^i q_i'\alpha) \rightarrow R_i'^{(-1)}(p)$ in the limit as $\alpha$ increases provided that the marginal rate of substitution $-U_2^i/U_1^i q_i'\alpha$ decreases with the reward level. (ii) Alternatively, and this is the device used most extensively, subjects are promised a "commission," $\beta$, for *each* transaction in addition to their cash trading profits. Now utility is $U^i\{R_i[q_i(E_i)] - (p-\beta)q_i(E_i), E_i\}$, and induced demand is

$$
\begin{aligned}
q_i &= R_i'^{(-1)}(p - \beta - U_2^i/U_1^i q_i') \\
&\cong R_i'^{(-1)}(p) \qquad \text{if } \beta \cong -U_2^i/U_1^i q_i' > 0.
\end{aligned}
$$

Compare two experiments (Charles Plott and Smith 1975, pp. 20–21) in which the induced supply and demand conditions were identical but one paid no cash trading commission, only trading profit, while the other paid both: In the one experiment,

volume was below (17–18 units) the "theoretical" equilibrium quantity (20 units) in all seven trading periods; in the second experiment, volume was below (19 units) equilibrium in only two of eight trading periods.

2. Individuals may attach game value to experimental outcomes. A profit in "points," $R_i(q_i)-pq_i$, may have subjective value $S_i[R_i(q_i)-pq_i]$. If $S_i$ is monotone increasing then such game utilities create no methodological problems since they reinforce rather than distort the effect of an explicit monetary reward structure. Because of such game utilities it is often possible in simple-task experiments to get satisfactory results without monetary rewards by using instructions to induce value by role-playing behavior (i.e., "think of yourself as making a profit of such and such when . . . "). But such game values are likely to be weak, erratic, and easily dominated by transactions costs, and subjects may be readily satiated with "point" profits.

Qualifications 1 and 2 are illustrated in the convergence behavior of three experimental markets with no cash rewards and seven markets with complete and with random cash rewards. In the first three cases subjects were asked to imagine that trading profits and commissions were real. In each case the market was organized as a continuous double auction. (Buyers could make oral bids and sellers oral offers for a single unit, and any seller could accept a bid, any buyer an offer. Each subject knew only his own demand or supply conditions.) (See Smith 1964, pp. 199–201 for the instructions.) In the first case (Smith 1962, p. 118, Chart 3) subjects trade only one unit per trading period. The absence of cash rewards does not hinder convergence to prices near equilibrium by the third trading period. However, deviations increase in period 4. In the absence of cash rewards this is more likely to occur as gaming boredom follows an initial (pleasant) experience of learning.

In a second experiment (previously unpublished) buyers received multiunit revenue (or resale value) schedules, and sellers multiunit total cost schedules. There were three buyers with one schedule, eight with another; four sellers with one cost schedule, eight with another. Now the task is more difficult and incentives are weak. Price convergence is strong, especially in the second period, since the greater volume when traders are given multiple-unit capacities increases the learning experience within a trading period. But volume is considerably below (24 and 26 units in the first and second periods) the competitive prediction (30 units). This is consistent with the above theory where the task is more difficult (higher transactions cost) and monetary rewards are absent.

Case 3 (Smith 1962, p. 119, Chart 4) illustrates an experiment which fails to reach either the competitive price or quantity although the market stabilizes nicely. In this case equilibrium requires contract prices to fall to the common limit price of all sellers. They are to "imagine" themselves as making a 5-cent commission on

TABLE 1—MEAN CONTRACT PRICE BY TRADING PERIOD

| Experiment | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
|---|---|---|---|---|---|---|---|
| Excess Supply | 5 | 5 | 5 | 5 | 8 | 8 | 8 |
| Reward Condition | Complete | Complete | Random | Complete | Complete | Complete | Complete |
| Information Condition | Incomplete | Incomplete | Incomplete | Complete | Incomplete | Incomplete | Complete |
| Trading Period 1 | 3.48 | 3.67 | 3.60 | 3.51 | 3.26 | 3.49 | 3.56 |
| Trading Period 2 | 3.29 | 3.26 | 3.44 | 3.40 | 3.15 | 3.28 | 3.25 |
| Trading Period 3 | 3.19 | 3.12 | 3.31 | 3.34 | 3.11 | 3.13 | 3.20 |
| Trading Period 4 | 3.14 | 3.10 | 3.24 | 3.37 | 3.10 | 3.12 | 3.17 |

trades at these limit prices, but clearly this is not real enough to induce many contracts at \$3.10 (the theoretical equilibrium). Not even a decrease in demand succeeded in lowering contracts to \$3.10 (Table 1). This contrasts with several experiments (1, 2, 5, 6 in Table 1) using complete cash rewards in which the supply and demand are even more asymmetric than in case 3. In Table 1, markets with an excess supply of five (eight) consisted of eleven buyers with limit prices \$4.20 and sixteen (nineteen) sellers with limit prices \$3.10. A different subject group participated in each double auction experiment. Convergence to the competitive price and quantity by trading period 4 was strong, although at the equilibrium price each buyer receives \$1.15 profit with commission per trade while each seller receives only the 5-cent commission.

A controlled measurement of the effect of complete versus random monetary rewards is shown in Table 1, experiments 1–3. In 1 and 2 all subjects were paid their trading profit plus commission in cash, while in 3 four of the 27 subjects were chosen at random to receive cash profits at the end of each trading period. The weaker random reward structure significantly retards the market's convergence.

Qualifications 1 and 2 lead to a precautionary corollary: with or without monetary rewards, the experimenter may be tempted to add "realism" by giving the abstract experimental commodity a name such as "wheat," or otherwise attempt to use instructions to simulate the alleged circumstances of a particular market. This runs the danger of so enriching induced values that control over valuation is lost. Suppose, as above, that a subject is paid $R_i(q_i)-pq_i$, but also perceives that he must attach instruction-induced value to $q_i$. Utility may now be $U^i[R_i(q_i)-pq_i,\ q_i]$, and demand becomes $q_i=R_i'^{(-1)}(p-U_2^i/U_1^i)>R_i'^{(-1)}(p)$. Consequently, it may be preferable *not* to embellish the instructions with well-intentioned attempts at "realism." Let the explicit reward structure be the singular source of valuation, insofar as this is possible.

3. Individuals may not be autonomous own-reward maximizers. Interpersonal utility criteria may qualify the theory of induced valuation. Thus subject $i$'s utility may depend upon both $i$'s and $k$'s reward, $U^i[R_i(q_i)-pq_i,\ R_k(q_k)-pq_k]$. If this condition prevails, then the demand of $i$ may depend upon that of $k$. However, this kind of interdependence is effectively controlled by the experimental condition of "incomplete" information, first defined and studied by Lawrence Fouraker and Siegel (1960, 1963) in experimental studies of bilateral bargaining and oligopoly. Under incomplete information subjects only know their own payoff contingencies. With $R_k(q_k)$ unknown to $i$, it cannot appear as a subjective argument of $U^i$.

The effect when subjects have complete information on each other's payoff contingencies is seen (Table 1) by comparing 1 (5) and 2 (6) with 4 (7). In 1 (5) and 2 (6) each subject knew only his own limit price. In 4 (7) the only change in the instructions was to add the information that there were eleven buyers, each with a \$4.20 resale value, and sixteen (nineteen in 7) sellers, each with unit cost \$3.10. From the mean price series it is seen that "complete" information of this kind retards the equilibrium tendencies of the double auction. Mean prices, especially in periods 3 and 4, tended to be higher under complete information than under incomplete information. The explanation is that with information on each other's payoffs, the way is open for "equity" considerations to modify self-interest choices. Sellers, believing that it is "fair" for trading profits to be shared between buyers and sellers, try to resist price decreases more vigorously than when they do not know what constitutes

such a fair price. Buyers acquiesce in this sharing by accepting many contracts well above $3.10, but since there is an excess of sellers, those holding out for the higher prices are the sellers most likely to fail to make contracts. Consequently, contract prices tend to decline, if slowly, when excess supply is 5, but more rapidly when excess supply is 8. The tendency of prices to be higher under complete information is contrary to the view of those who have argued that "perfect" information is essential for establishing competitive prices. The results are consistent with the game-theoretic proposition that more information increases the prospect of collusion (Shubik 1959, p. 171), and with the results of Fouraker and Siegel (1963, p. 187) in which the tendency of the competitive equilibrium to prevail under duopoly bargaining is reduced under complete information.

# THE APPLICATION TO ECONOMICS OF DIFFERENTIAL TOPOLOGY AND GLOBAL ANALYSIS

# Regular Differentiable Economies

*By* GERARD DEBREU*

The recent introduction of differential topology into economics was brought about by the study of several basic questions that arise in any mathematical theory of a social system centered on a concept of equilibrium. The purpose of this paper is to present a detailed discussion of two of those questions, and then to make a rapid survey of some related developments of the last five years.

Let $e$ be a complete mathematical description of the economy to be studied (e.g., for an exchange economy, $e$ might be a list of the demand functions and of the initial endowments of the consumers). Assumptions made a priori about $e$ (e.g., assumptions of continuity on the demand functions) define the space $\mathcal{E}$ of economies to which the study is restricted. By a state of an economy we mean a list of specific values of all the relevant endogenous variables (e.g., prices and quantities of all the commodities consumed by the various consumers). We denote by $S$ the set of conceivable states. Now a given equilibrium theory associates with each economy $e$ in $\mathcal{E}$, the set $E(e)$ of equilibrium states of $e$, a subset of $S$.

As a first test of the adequacy of this mathematical model, it must be possible to prove that for every element $e$ of a sufficiently broad class $\mathcal{E}$, the set $E(e)$ is not empty. This is the existence problem that has been extensively studied during the last decades. Mentioning only the early contributions of John von Neumann and Abraham Wald, I refer to the comprehensive survey of the literature by Kenneth Arrow and F. H. Hahn. The mathematical tools for the solution were provided by

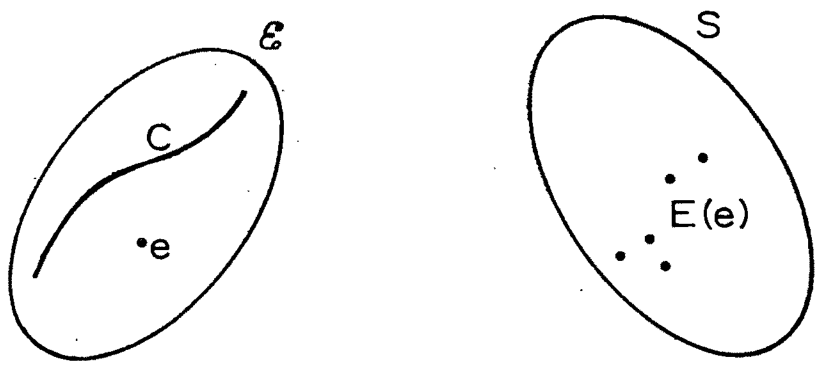

FIGURE 1

algebraic topology in the form of fixed point theorems, or directly related results. An alternative approach of the last ten years, associated mainly with the name of Herbert Scarf, has consisted of developing efficient algorithms for the computation of an approximate equilibrium. The mathematical techniques used here were those of combinatorial topology.

Having obtained a general solution to the existence problem, one must investigate the structure of the set $E(e)$ of equilibria of the economy $e$. Consider an economy that has an equilibrium $x$ such that in any neighborhood of $x$, there are infinitely many other equilibria. In this situation the explanation of equilibrium is essentially indeterminate, at least near $x$. Moreover the economic system $e$ is unstable in the sense that arbitrarily small perturbations from $x$ to a neighboring equilibrium induce no tendency for the state of the economy to return to $x$. It is therefore highly desirable to have an economy $e$ for which the set of equilibria is *discrete*, i.e., such that for every equilibrium $x$ in $E(e)$, there is a neighborhood of $x$ in which $x$ is the unique equilibrium of $e$. Unfortunately, even if every agent in the economy $e$ is mathematically very well-behaved, one may obtain a set $E(e)$ that is not discrete (in the simplest case of an exchange economy with two consumers and two commodities, one can easily find in the associated Edgeworth box a set $E(e)$ made up of a continuum of points). The pathology is due to the manner in which the agents are matched, a situation entirely different from that of existence theory where it was possible to give general conditions on the behavior of each agent separately ensuring that the set $E(e)$ would not be empty.

The way out of this difficulty is provided by differential topology. It consists of making suitable differentiability assumptions on the functions entering the description of $e$ (e.g., demand functions are assumed to be continuously differentiable), and to define a concept of *regular* economy such that (a) the critical set $C$ of nonregular economies is a negligible subset of $\mathcal{E}$, and (b) every regular economy has a discrete set of equilibria.

Actually an adequate model $e$ of the economy must have still another property. Specifically if $e'$ is close to $e$, then one would like the set of equilibria $E(e')$ to be close to $E(e)$. Otherwise an arbitrarily small error in the determination of the characteristics of $e$ would yield an entirely different set of equilibria, thus depriving the theory of much of its explanatory power. Therefore it is also desirable for the definition of regularity to be such that (c) in a neighborhood of a regular economy, the set of equilibria depends continuously on the economy. The questions of discreteness of the set of equilibria and of continuous dependence of the set of equilibria on the economy, or closely related questions, have a long history in the study of physical systems. The recent work of R. Thom has considerably extended the range of their applications, in particular to biological systems. These questions clearly have no less relevance for social systems.

The solution of the problem that has just been outlined rests on A. Sard's theorem which Thom once characterized as one of the three main results of Mathematical Analysis. Consider a continuously differentiable function $f$ from the real line $R$ to $R$, and define a *critical point* as a point $x$ where the derivative of $f$ vanishes. The set of critical points of $f$ can obviously be large. In the extreme case of a constant function it is the whole of $R$. Define now a *critical value* of $f$ as the image of a critical point. In Figure 2 three critical values $y^1$, $y^2$, $y^3$ are displayed.

One feels that the set of those critical values is necessarily small, and indeed Sard's theorem asserts that it is negligible. To be precise, it has (Lebesgue) *measure*

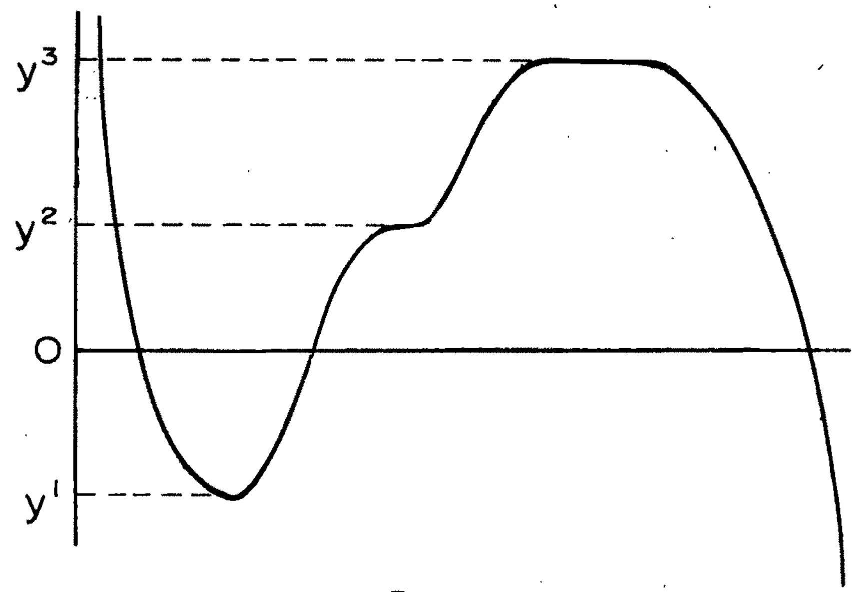

FIGURE 2

*zero*. In other words, given an arbitrarily small positive number $\epsilon$, one can find a countable collection of intervals such that their union covers the critical set, and that the sum of the lengths of these intervals is smaller than $\epsilon$. Sard's theorem holds as well for a continuously differentiable function $f$ from an $m$-dimensional Euclidean space to an $m$-dimensional Euclidean space. Here a *critical point* of $f$ is a point where the determinant of the Jacobian of $f$ vanishes. As before, a *critical value* of $f$ is the image of a critical point, and the set of critical values has measure zero, i.e., it can be covered by a countable collection of $m$-dimensional cubes of arbitrarily small total volume. A *regular value* of $f$ is, by definition, a noncritical value.

Sard's theorem is valid in still more general conditions. In order to present a stronger version that we will use later on, we need the concept of a (differentiable) manifold. A function $g$ from an $n$-dimensional Euclidean space to an $n$-dimensional Euclidean space is said to be a *differentiable isomorphism* if it is one-to-one, and if $g$, as well as its inverse $g^{-1}$ are continuously differentiable. Differential topology studies properties that are invariant under differentiable isomorphisms, a principle

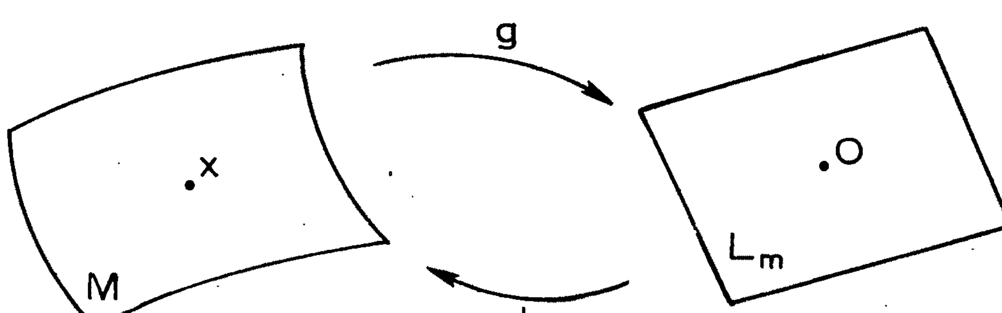

FIGURE 3

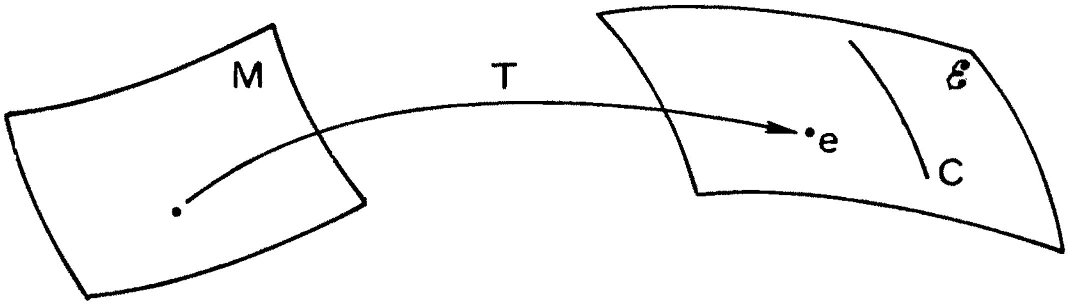

FIGURE 4

that leads to the following definition. A subset $M$ of a Euclidean space $L$ is an $m$-dimensional (differentiable) *manifold* if for each point $x$ of $M$ there is an $m$-dimensional linear subspace $L_m$ of $L$ such that a neighborhood in $L$ of $x$ and the part of $M$ that it contains are differentiably isomorphic to a neighborhood in $L$ of $O$ and the part of $L_m$ that it contains. In other words, at every one of its points, $M$ is locally an $m$-dimensional Euclidean space up to a differentiable isomorphism. Clearly one can do differential calculus on manifolds exactly as on Euclidean spaces; one can also easily define a subset of measure zero of a manifold $M$. Then the statement of Sard's theorem becomes: if $f$ is a continuously differentiable function from an $m$-dimensional manifold $M_1$ to an $m$-dimensional manifold $M_2$, the set of critical values of $f$ has measure zero in $M_2$.

To illustrate these general principles, assume that the economy $e$ can be characterized by finitely many real parameters, or more precisely, that $\mathcal{E}$ is a finite-dimensional manifold. A simple strategy for showing that almost every economy in $\mathcal{E}$ is well-behaved consists of introducing a manifold $M$ of the same dimension as $\mathcal{E}$, and a continuously differentiable function $T$ from $M$ to $\mathcal{E}$ such that a *regular* economy, defined as a regular value of $T$, actually has properties (b) and (c). Sard's theorem implies that the set $C$ of critical economies has measure zero.

To give an even more specific illustration, we consider an exchange economy with $l$ commodities, $m$ consumers, and fixed demand functions. Therefore the parameters of the economy are the initial holdings of each commodity by each consumer, a list $e$ of $lm$ positive numbers. We denote by $\mathcal{E}$ the set of those $lm$ lists, and we observe for later use that the dimension of $\mathcal{E}$ is $lm$. The state of the economy is taken to be the price-system, i.e., a list $p$ of $l$ positive numbers. Since multiplying all prices by the same positive number does not affect the behavior of the agents, we can normalize the price-system and restrict it to belong to a manifold $S$, such that dim $S=l-1$, for instance $S$ may be the positive part of the unit sphere in the $l$-dimensional Euclidean space. Given the economy $e$ and the price-system $p$, we write the $l$-list of the excesses of demand over supply on every market as $F(e, p)$, a vector in the $l$-dimensional space $R^l$. The price-system $p$ is an equilibrium state if and only if

$$F(e, p) = 0. \tag{1}$$

Given $e$, the set of $p$ satisfying (1) is $E(e)$. However, the excess demand function $F$ obeys Walras' law. Namely for every $e$ and $p$, the value of the excess demand equals 0; i.e., $p \cdot F(e, p)=0$. Consequently the equilibrium condition (1) is equivalent to equating to $O$ the list $\hat{F}$ of the first $l-1$ components of $F$,

$$\hat{F}(e, p) = 0. \tag{2}$$

Now if the individual demand functions are continuously differentiable, we can follow the strategy we have outlined above in several ways. An elementary treatment that does not use the concept of a manifold can be given as in Debreu (1970, 387–392). An alternative, and more satisfactory, solution takes as a central concept the set $M$ of pairs $(e, p)$ in the Cartesian product $\mathcal{E} \times S$ satisfying (2) (Stephen Smale 1974, pp. 1–14, Y. Balasko 1975, pp. 95–118). The space $\mathcal{E} \times S$ is of dimension $lm+l-1$, and the equilibrium condition (2) imposes $(l-1)$ restrictions on the pair $(e, p)$. Therefore one may expect $M$ to be a manifold of dimension $lm$, i.e., of the same dimension as $\mathcal{E}$. Indeed this is easily shown to be the case. The function $T$ from the *equilibrium manifold* $M$ to $\mathcal{E}$ could hardly be simpler; it is the transformation $(e, p) \mapsto e$, i.e., the projection from $M$ into $\mathcal{E}$. A regular economy is then defined as a regular value of $T$. Equivalently $e$ is a regular economy if for every $(e, p)$ in $M$ projecting into $e$, the projection of the tangent space of $M$ at $(e, p)$ covers $\mathcal{E}$. Three critical economies $e^1$, $e^2$, $e^3$ are displayed on Figure 5. Sard's theorem yields the conclusion that (a) the set $C$ of critical economies has measure zero.

Given a regular economy $e$ in $\mathcal{E}$ (as on Figure 5), one obtains the set $E(e)$ of equilibrium price-systems $p$ by taking in $M$ the set $T^{-1}(e)$ of inverse images of $e$ by the projection $T$, and by projecting $T^{-1}(e)$ into $S$. At every point of $T^{-1}(e)$, the determinant of the Jacobian of $T$ is different from $O$, and a direct application of the inverse function theorem yields that $T^{-1}(e)$ is a discrete subset of $M$. The pathologies associated with critical economies are made clear by Figure 5. For instance the economy $e^1$ has a discrete set of (two) equilibria, but a continuous displacement of the economy in a neighborhood of $e^1$ produces at $e^1$ a sudden change in the set of equilibria. In particular, consider $e$ on the right of $e^1$ and the associated equilibrium $p$ on the upper branch of $M$ (as on Figure 5). When $e$ moves left, follow $p$ by continuity. As $e$ crosses $e^1$, the equilibrium state of the system jumps to the lower branch of $M$. The economy $e^3$ has a continuum of equilibria and an isolated equilibrium. At the point $e^3$ one also observes a sudden change in the set of equilibria for a continuous displacement of the economy in a neighborhood of $e^3$. Although the economy $e^2$ is critical, it

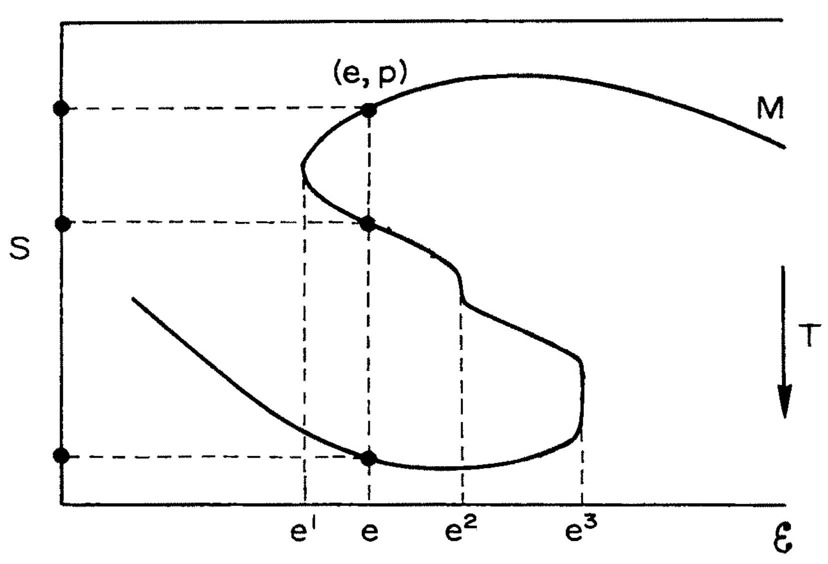

FIGURE 5

has a discrete set of (three) equilibria, and in a neighborhood of $e^3$, the set of equilibria depends continuously on the economy.

One can obtain considerably stronger conclusions by making suitable assumptions on the behavior of the excess demand function $F$ near the boundary of $S$. For instance, assume that given $e$, the excess demand $F(e, p)$ is unbounded when the price of a commodity tends to zero. In this case the set $C$ of critical economies is *closed* in addition to being of measure zero, and is therefore negligible in a strong sense. Moreover ($b'$) every regular economy has a *finite* set of equilibria, and ($c'$) in a neighborhood of a regular economy, the set of equilibria depends in a *continuously differentiable* manner on the economy.

Property ($c'$), which strengthens property ($c$) of continuous dependence of the set of equilibria $E(e)$ on the economy $e$, has made it possible to answer the question of the rate of convergence of the core of an economy. Many authors from Edgeworth to W. Hildenbrand have shown with increasing generality that the core and the set of Walras equilibria of an economy tend toward each other as the number of agents increases in such a way that every one of them becomes insignificant. This precise formulation of the idea that an economy tends to become more competitive under these conditions raises the question of the rate of that convergence. A conjecture of Shapley (1975, pp. 345–51) has led to the proof (Debreu, 1975, pp. 1–7; B. Grodal, pp. 171–186) that outside the negligible critical set, the core and the set of Walras equilibria converge to each other at least as fast as the reciprocal of the number of agents converges to zero.

The results on negligible sets of critical economies that we have presented have been considerably extended by Balasko, Chichilnisky, Delbaen, E. and H. Dierker, Fuchs, K. Hildenbrand, Ichiishi, Kalman, Laroque, Mas-Colell, Mitiagin, Rader, Schecter, Smale, and Varian. In particular, the demand functions of the consumers, which we assumed to be fixed, have been treated as variables; economies with many agents, or with many commodities have been taken into account; production has been introduced into the model; demand functions have been replaced as primitive concepts by utility functions or by preference relations, neither of which are restricted to satisfy convexity assumptions. However in most of these extensions the description of the economy requires infinitely many real parameters, i.e., the dimension of the space $\mathcal{E}$ of economies is infinite, and it is no longer possible to use the previous measure theoretical definition of a negligible set. One can now prove only that in the space $\mathcal{E}$, the critical economies form a *closed subset $C$ whose interior is empty.*

The introduction of differential topology into economic theory has made necessary a reexamination of several classical problems, for instance that of differentiable preference relations. In particular, Smale has played a leading role in extending, simplifying, and making more rigorous the study of the set of Pareto optima, and of dynamic processes converging to that set, a program of research in which de Melo, Ong, Simon, Titus, and Y. H. Wan have participated. But of special importance among the applications of Global Analysis to economics has been Smale's recent work on Global Newton Methods where he gives a differential analog of the Scarf-Eaves algorithm for the computation of an economic equilibrium, unifying their approach with the traditional dynamic economic processes of Samuelson, and of Arrow, Block, and Hurwicz.

# Dynamics in General Equilibrium Theory

By STEPHEN SMALE*

I find myself something of an outsider in writing a paper like this; and for a mathematician to write a paper with no technical mathematics is a real (but very constructive) confrontation with the problem of communication. What I hope to achieve here is to convey some of my ideas on the relation between dynamics and the traditionally static, economic equilibrium theory.

Since I have been working in mathematical economics, I have been struck by the number of attacks on general equilibrium theory, on mathematical economics and even economic theory in general. Coming from a radical background, I have much sympathy for some of the arguments brought forth.

I first want to say a few words on the subject of mathematics in economics and economic theory in general. The role of theory per se hardly requires defense; theory can give a deeper understanding of any subject, subtle relations are seen, inconsistent ideas are exposed, new horizons are revealed.

A criticism commonly made of economic theory is its failure to make predictions of crises in the country or to anticipate correctly unemployment or inflation. One must be cautious in the social sciences about looking toward physics for answers. However, some comparisons with the physical sciences seem profitable in connection with the above criticism. In those sciences, where theory itself is in a far more advanced state, limitations can be seen in a similar way. For example a given individual human body functions according to physical principles; however no physical scientist would predict a heart attack. The physical theory gives understanding of aspects of what goes on in the human body only under very idealized conditions. The physical theories eventually play some role in the education of medical doctors, who can then say some things, some times about a patient's susceptibility to a heart attack, preventive measures, and cures.

The economy of the world or even a nation is a very complex phenomenon, like a human body, involving a number of factors, both economic and political. It is no more reasonable to expect economic theorists to predict a nation's economic future than for a theoretical scientist to predict the future health of an individual.

Questions about the need for mathematics in economic theory have been raised. Indeed, the successes of mathematics in economics have not been nearly as impressive as in physics. Yet the notion of money and prices already introduces mathematics into economics; and the mathematics becomes deeper with the equation of equilibrium, supply equals demand. When one considers the equation, supply equals demand for several interdependent markets, the mathematical problem already takes on some sophistication.

What is special about "general equilibrium theory" as opposed to economic theory in general? For me the importance

* Dept. of Mathematics, University of California, Berkeley.

of general equilibrium theory lies in its traditions which are deeper than any other part of economic theory. These traditions, which of course derive from actual economic history, explain why equilibrium theory has played such a central role and possesses such depth in content. Many of the procedures and mathematical methods used in other parts of economics grew out of developments in general equilibrium theory. Also equilibrium theory plays an important role in communication within the economics profession. Since most economists are knowledgeable in equilibrium theory, they can understand new ideas more readily when presented in that context. Also, since equilibrium theory has been studied so much, new ideas introduced there show weaknesses and also strengths most quickly.

After all of this is said, equilibrium theory will eventually stand or fall, depending on its truth as an important idealization of actual economic systems or as a model with values of justice, of efficient distribution and of utilization of resources. As a normative theory, I find great merit in its decentralization features (Schumacher's popular book, "Small is Beautiful" expresses some of my sentiment on decentralization). There are also, without doubt, basic failings in the theory which are well-presented in the economic literature, and there are some weaknesses which I wish to discuss presently. In fact these problems can be seen and understood especially clearly due to the well-developed structure of the theory; and one can use the body of general equilibrium theory as a tool in developing alternate models. To me it would seem overly difficult to construct and communicate successfully any alternate economic theory without having first studied very thoroughly equilibrium theory.

I would like to give some reasons why I feel equilibrium theory is far from satisfactory. For one thing the theory has not successfully confronted the question, "How is equilibrium reached?" Dynamic considerations would seem necessary to resolve this problem. Another weakness is the reliance of the theory on long range optimization.

In the main model of equilibrium theory, say as presented in Gerard Debreu's *Theory of Value,* economic agents make one life-long decision, optimizing some value. With future dating of commodities, time has almost an artificial role. The model is reminiscent of John von Neumann's game theory. I like to make an analogy between "Theory of Value" and the game theoretic approach to chess. The possible strategies are laid out to each player in advance, paths in a game tree, or a set of moves, one move to each position that could possibly occur. Each player makes a single choice of strategy. The strategies are compared and the game is over. Of course, chess isn't played like this. And in a situation more complicated than chess, where life-long consumption plans replace strategies, I don't believe economic agents act that way either.

In fact even the very best chess players don't analyze very many moves and certainly don't make future commitments. Their experience together with the environment at the moment (the position), some rules of thumb and some other considerations lead to decisions on the playing board.

My personal economic decisions are of a similar nature, from buying a book to buying a house; from a decision to travel to decisions about my job. Between one economic decision and another, there has been a real passage of time, circumstances have changed, and the new decision takes place in this new environment.

Long-run optimization would be im-

practical, even if it were emotionally acceptable, because of barriers of complexity. Complexity keeps us from analyzing very far ahead. The amount of time involved in making a decision is an important factor, for a chess player or a purchaser. Dynamic models based on some kind of behavioral strategy could meet these objections.

Sometimes static theories pose paradoxes whose resolution lies in a dynamic perspective. Let me give an example from the theory of duopoly of the Cournot (or Nash) equilibrium solution. Under classical hypotheses on the profit functions, consider such an equilibrium $(r_1, r_2)$ where $r_i$ is the rate of production of duopolist number $i$. Then agent 1's rate of production maximizes profit among all such rates with $r_2$ fixed. On the other hand the solution is unsatisfactory because there is another state, say, $(r'_1, r'_2)$, where each duopolist with reduced production is taking a higher profit. In the actual dynamic world it is unlikely that the duopolists would stay at the Cournot solution, knowing that they would both be better off at nearby states.

It doesn't require explicit cooperation for these agents to move off the Cournot solution. In fact with flow of information and implicit threats in the context of a passage of time, one can argue that the duopolists will move to an optimal state from a Cournot state. But this resolution requires a real passage of time, that after each market move, the opposing duopolist has another opportunity to move. One can readily think of examples of duopoly where an increase of advertising is withheld by one agent knowing the other agent would match an increase and both would be worse off. James Friedman has written on this topic.

I feel that dynamics could also play a role in the resolution of Kenneth Arrow's paradox in the politics of social choice. Politics and elections in particular are actually part of a dynamic process, balloting being just a stage. The process looked at as a whole involves a number of moves such as a candidate's speech, a political ad, revising a position on some issue, etc. After each action of a candidate, other candidates have the option of taking an action of their own; voters' opinions evolve. For this reason, I would think that a dynamical model of the political process would give much better perspective than a static model of simple voting. In relation to this, the work of G. Kramer comes to mind.

We return to the subject of equilibrium theory. The existence theory of the static approach is deeply rooted to the use of the mathematics of fixed point theory. Thus one step in the liberation from the static point of view would be to use a mathematics of a different kind. Furthermore, proofs of fixed point theorems traditionally use difficult ideas of algebraic topology, and this has obscured the economic phenomena underlying the existence of equilibria. Also the economic equilibrium problem presents itself most directly and with the most tradition not as a fixed point problem, but as an *equation*, supply equals demand. Mathematical economists have translated the problem of solving this equation into a fixed point problem.

I think it is fair to say that for the main existence problems in the theory of economic equilibria, one can now bypass the fixed point approach and attack the equations directly to give existence of solutions, with a simpler kind of mathematics and even mathematics with dynamic and algorithmic overtones. In the last part of the paper we elaborate on this point.

Behind my own work on the questions of dynamics in economics, lies certain foundational work in the equilibrium theory in terms of calculus. The early

development of mathematical economics, including the 19th century and even up to World War II, was largely in terms of calculus; it was no doubt the influence of game theory, and associated fixed point theorems that gradually reduced the dependence on calculus. In *Theory of Value* in 1959, Debreu wrote of the work of von Neumann and Oskar Morgenstern which freed mathematical economics from its traditions of differential calculus and compromises with logic. He wrote of the radical change of mathematical tools from calculus to convexity and topology.

But then in his paper on a finite number of equilibria, Debreu returned to calculus tools; my own work, "Global Analysis and Economics," has been to try to systematize the use of calculus in equilibrium theory. This can be justified on several grounds. First, the theory is brought closer to the practice. With calculus, one has in the derivative a linear approximation. It is these linear conditions that are so basic to practical economic studies. Comparative statics depend on derivatives; the same is usually true for stability conditions; dynamic questions are more accessible via calculus. When general equilibrium theory is developed on calculus mathematics, not only is theory brought closer to practice, but greater unity is achieved. Furthermore, recent work on approximation by differentiable functions in economics gives further justification to the use of calculus.

Finally before moving to the constructive side of the question of dynamics in equilibrium theory, it is worth making a remark on the nature of goods. It seems from our experience that it is important especially in modeling dynamics to put goods into two ideal classes, either completely perishable or completely durable. The theory seems different for the two kinds. For example, Walras equilibrium seems suited to the perishable, continually endowed class of goods, while for durable goods, the kind of equilibrium found in the fundamental theorem of welfare economics seems more appropriate. We hope that the rest of the paper makes this point clearer.

We discuss now the results of our paper, "Exchange Processes with Price Adjustment." This is a model of a market of durable goods; a particular example from personal experience of such a market is a weekend "mineral bourse" where agents with minerals and/or money meet to exchange, buy, and sell fine mineral specimens for collectors. Here one sees a truly dynamic process of exchange and price adjustments which converges to an equilibrium toward the end of the weekend of the "bourse."

An early work in some of the same spirit was done in 1962 by Frank H. Hahn, Hirofumi Uzawa, and Takashi Negishi. This approach is called a "nontatonment," because in place of the Walrasian Tatonment, a sequence of actual trades takes place over time. On the other hand, our model differs from the 1962 work in that it is nondeterministic, the dynamics proceeds without an ordinary differential equation, long-run optimization is dropped, and a large body of examples is constructed.

The main result of our paper can be stated as follows:

"In a pure exchange economy, an exchange price adjustment process, responsive to transaction costs, and which doesn't stop unless forced to by market conditions, converges to a price equilibrium. There exists such processes starting from any state of any (pure exchange) economy."

In the paper, mathematical content is given to all of the phrases used here, and the result is proved. Here we give a brief explanation of some of the terms used.

A "state" of an economy means a set of

data characterizing the economy at a given time. Our use of the word "state" is akin to its use in physics. For example in a pure exchange economy, a state will consist of an allocation of the resources, or equivalently the set of goods of each agent and a price system.

A state in general will change over time, e.g., by exchange and price adjustments. Thus a "process" as used in the main result, means a passage in time of a state. Or equivalently, a process is a path (over time) in the space of states of an economy.

This process, to qualify as an *exchange* process, must satisfy economically justifiable conditions for exchange which are embodied in the following axiom. The exchange axiom for the process asserts that: (a) the total resources of the economy are constant (there is no production); (b) exchange takes place at current prices; (c) an exchange increases satisfaction of the participating agents; and (d) some exchange will take place provided that it is possible consistent with (a), (b), and (c).

For the process to qualify as a price adjustment process (as in the quoted main result), we demand that it satisfy a price adjustment axiom defined in terms of a short run version of demand. A usual excess demand approach requires long-run optimization for the agents while our spirit is closer to that of behavioral strategies. At given prices and goods possessed one defines the infinitesimal demand of an agent to be the direction his preferences take him when restricted to his budget set.

The price adjustment axiom asserts that prices adjust in the direction of some weighting of the infinitesimal demands of all the agents.

A Walrasian price equilibrium depends on the traders' endowments. Thus if one allows a real passage of time, say an actual exchange to take place, and several such, this initial endowment becomes forgotten. Thus if one allows a "nontatonment" kind of time passage, one must replace a Walrasian price equilibrium by a different notion of price equilibrium.

As stated in our main result above, a price equilibrium is a feasible allocation and price system where, for each agent, satisfaction is maximized on his budget set defined relative to his wealth at equilibrium. Equivalently, a price equilibrium is an optimal allocation together with a supporting price system, as studied in the correspondence of the fundamental theorem of welfare economics.

A detailed mechanism of price setting and transactions is not developed, but it seems likely that the model is consistent with doing this explication.

Next we discuss some problems and results on the classical Walrasian model from the point of view of dynamics and algorithms. We prefer an alternate, well-known interpretation of the Walras model to that given in Debreu's *Theory of Value*.

Suppose that the goods are perishable, with labor a main example. One might envision a situation where each day an agent starts his economic activity with a fixed endowment of labor, or fish which won't keep. The next day he will have a new endowment of the same, but none left from the day before.

The consumption variables are the amounts of commodities consumed each day, of an agent. Thus both the endowment and consumption bundles in commodity space will be interpreted as the *rates* of endowment (fixed over time) and consumption respectively. A completely satisfactory dynamics (which isn't available) for this problem would construct and analyze paths over time in the space of states, that is commodity vectors for each agent and price systems (or sets of price systems). These paths should obey economically justifiable axioms of exchange and price adjustment, and

probably should lead, at least under some economic conditions to a Walrasian equilibrium, starting from an endowment allocation and any price system. At the most satisfactory level, these paths should be given interpretations in terms of individual agent's actions in price offerings and purchases. In my view, a behavioral strategy for agents would be more desirable than decisions based on long run optimization.

Martin Shubik and I have worked on the problem in this setting without any definite success. On the other hand, it seems as if we might eventually obtain such a model with convergence provided a condition such as gross substitutes is satisfied. I should emphasize that I am not talking about any "tatonment" in this kind of dynamic, but rather an actual process, where agents are adjusting their goals, consumptions, prices over time to arrive at balanced budgets where the value of the rate of consumption equals the value of the rate of the fixed endowment for each agent.

I would like to turn now to some work carried out in my article "A Convergent Process of Price Adjustment and Global Newton Methods," which has more success on the mathematical side of the above problem.

One way of looking at this work is to first alter the Scarf Algorithm from finding fixed points to solving a system of equations, especially the system, supply equals demand in many variables. We define an ordinary differential equation, called a "global Newton," which is a version of (the altered) Scarf's Algorithm. Under rather general hypotheses (comparable to those needed in the execution of Scarf's Algorithm), solutions of the global Newton converge to the set of solutions of the original system (e.g., supply equals demand). Combining this fact with methods of numerical analysis, one obtains a different but analogous algorithm to that of Scarf. Morris Hirsch and I have implemented this effectively on a computer and are developing the algorithm from a numerical analysis point of view. It applies to systems of $n$ nonlinear equations in $n$ variables, without hypotheses on the system of nonzero Jacobian, convexity, or monotonicity.

Let $z(p)$ be the excess demand as a function of prices $p=(p_1 \ldots p_l)$ so that $p^*$ is an equilibrium if $z(p^*)=0$. Then the global Newton takes the form

$$(1) \qquad Dz(p)\frac{dp}{dt} = -\lambda z(p),$$

$$\operatorname{sign} \lambda = \operatorname{sign} \text{Determinant } Dz(p)$$

Here $Dz(p)$ is the matrix of first partial derivatives of $z$. If one takes $\lambda=1$ and uses Euler's method of discrete approximation to (1) then one obtains Newton's method for solving $z(p)=0$. Using equation (1), one can obtain a proof of the existence of economic equilibrium without using fixed point theorems or algebraic topology.

Consider the problem of representing a process of price adjustments by (1). Recall that the classical "tatonment" process has an embodiment in the equation

$$(2) \qquad \frac{dp}{dt} = z(p)$$

Arrow, Leonid Hurwicz and Herbert Block have shown that solutions of (2) converge to economic equilibrium under hypotheses on $z$ such as gross substitutes. These hypotheses are substantial and are strong enough to imply the existence of a unique equilibrium. On the other hand Scarf subsequently showed that under classical properties on preference relations, almost all solutions of (2) could oscillate for all time.

Now (1) can be considered as a modification of (2), which involves more subtle intermarket relations and which will con-

verge when (2) doesn't. In particular (1) will converge in the Scarf example.

Generally speaking, (1) converges starting from almost any initial price system on the boundary of the price simplex. One could also formulate the equation in quantity space and look for an interpretation of the process in terms of budget balancing actions on the part of the agents. The interested reader could pursue these topics further in the papers cited.

# NEW DEVELOPMENTS IN LABOR MARKET DYNAMICS

# Labor Force Participation and Earnings in a Demographic Model of the Labor Market

*By* RICHARD S. TOIKKA AND CHARLES C. HOLT*

A structural model of the labor market should improve our understanding of and ability to predict unemployment and wage change. With such a model of the labor market and the inflation process we should be better able to prescribe policies for aggregate demand and for structural improvements that are designed to reduce inflation and unemployment.

Because labor market dynamics are fast, the duration of unemployment being only a few months, a structural model to reflect turnover and search behavior must have a very short period—a quarter would be too long. However, since real wages change sluggishly, the usual allocation variables will not be fully effective in regulating the turnover and search behavior of workers and employers. Hence, we expect that the short-term dynamics of the labor market will be regulated primarily by the *availability* in the market of jobs and workers. The composition of unemployment shows wide disparities for different demographic groups which suggests the desirability of separately estimating their search and turnover behaviors.

## I. The RASST Model and Its Extensions

A group at The Urban Institute has estimated, tested and applied a structural model of the labor market, Race Age Sex Search Turnover (*RASST*), that distinguishes for each of sixteen age-race-sex groups six monthly flows between employment, unemployment and out-of-the-labor force.[1] This model is driven by exogenous jobs and the population sizes of the groups. Its transition probabilities are governed by the cyclical availability measured by the vacancy to unemployment ratio, seasonal dummies, and time trends.

This model has been used in 1974 to predict the composition of unemployment, employment, and labor participation for the recession year 1975, and more recently for 1976 based on administration forecasts of aggregate demand conditions. *RASST* also has been used to define the concept of "jobless rate" obtained by subtracting current employment from full employment labor force, which is based on current demographic composition and behavior. (See Smith and Vanski, 1975.)

Although the *RASST* model has performed well, it requires important extensions in order to be of maximum relevance for the analytic and policy uses discussed above. The extensions which we discuss here fall into the following two areas:

* The Urban Institute.

[1] For reference see Ralph E. Smith *et al.* (1974), Smith (1974), and Smith and J. E. Vanski (1975). Somewhat parallel work has been done in Canada. See Frank T. Denton *et al.*, (1975a) and (1975b).

(1) The transition probabilities that determine the search-turnover flows and in turn the stock of unemployed workers are, of course, not allocated by availability alone. Real wages and family earnings also affect worker decisions particularly to enter and leave the labor force, and very likely to quit low paid jobs. These effects should, if possible, be added to the model.

(2) To generate these wages and earnings for the demographic groups and to contribute to the explanation of wages in the inflation process, additional relations are needed. The explanatory variables should include price level changes (or better yet expectations), demographic and aggregate unemployment, discouraged worker (possibly by use of the jobless rate), relative wage levels, and proxies for family income (earned and unearned). Introducing earning as well as wage rates would require the model to generate an hours worked variable per month to complement employment, which already is generated.

## II. A Dynamic Theory of Labor Force Participation

A dynamic behavioral theory of labor force participation should begin with an analysis of household behavior. Decisions by family members determine labor force withdrawal and labor force entry. Aggregation of these discrete events at a point in time produces flows of persons changing labor force participation status.

A household may be thought to consist of a group of persons who make joint decisions to divide their time between market work. job search, and leisure or homework. Since our empirical analysis uses the monthly Current Population Survey (*CPS*) data on labor force status, it is convenient at the outset to make our theoretical constructs consistent with the *CPS* data. A person who spends any time at paid work will be considered to be "employed" ($E$). A person who spends no time at paid work but devotes some time to job search will be considered to be "unemployed" ($U$). Finally, a person who spends no time at paid work or search will be considered "not in the labor force" ($N$). Using these three labor force categories we characterize the labor market as a three-state Markov probability process.

The labor force participation dimensions of this Markov process are summarized in three transition probabilities: labor force entrances, labor force withdrawals by the unemployed, and labor force withdrawals by the employed. In general the costs and benefits of making a labor market transition are conditional on the person's current labor force status. For example, the cost of leaving the labor force is likely to be less for an unemployed worker than for an employed worker. This observation is borne out by empirical data from *CPS* which indicate that unemployed persons leave the labor force at a rate which is 7 times that for employed persons.[2]

The theory which is appropriate for analyzing the choice made by persons and households in this Markov process framework is Markov decision theory. A person's decision to change or not to change his labor force state is the outcome of a dynamic programming problem in which future utilities are dependent on the state occupied and decision variables.[3]

The structure of relative utilities will depend on relative preferences for nonmarket activities and earnings opportunities in the market sector. Preferences for

[2] This figure varies dramatically by demographic group. See Smith (1974).

[3] For a treatment of this decision problem in a dynamic programming framework, see Toikka (1975).

nonmarket activities will depend on a person's age, sex, family situation, etc. In our empirical analysis we stratify our sample by age, race, and sex to capture differences in preferences for nonmarket activity. Since opportunities for nonmarket activity are to some extent stochastic, being influenced by such factors as births, deaths, illness, and family separations, the utility of nonmarket activity has a random component which may account for frequent changes in an individual's labor force participation.

The utility of nonmarket activity $U(N)$ will be specified as a stochastic function of seasonal dummies $(D_1, \ldots, D_{11})$, and family income $(Y)$. The family income variable is positively correlated with the utility of nonmarket activity if household production is a normal good. Thus,

$$(1) \quad U(N) = b_0 + b_1 Y + \sum_i \alpha_i D_i + \epsilon \qquad b_1 > 0$$

The earnings from market work $(W)$ will be used as a measure of the utility of market activity. In the simplest kind of model, a person changes labor force participation status when the resulting change in utility net of transition costs is positive.

The probability of a person leaving the labor force when employed should vary inversely with earnings from market work and directly with the utility of nonmarket activity, so that:

$$(2) \qquad P(EN) = g[\overset{(-)}{W}, \overset{(+)}{U(N)}]$$

where (signs) denote the signs of the partial derivatives. Substituting (1) into (2) we get:

$$(3) \quad P(EN) = g[D_1, \ldots, D_{11}, \overset{(-)}{W}, \overset{(+)}{Y}]$$

Similar considerations apply with respect to the decisions to enter the labor force and to leave it when unemployed. In an expected utility maximization framework, these decisions are made by comparing the expected utility of job search with the expected utility of nonmarket activity. The probability of labor force entry $P(NL)$ varies directly with the (expected) utility of job search $U(S)$ and inversely with the (expected) utility of nonmarket activity $U(N)$. Thus,

$$(4) \qquad P(NL) = e[\overset{(+)}{U(S)}, \overset{(-)}{U(N)}]$$

Conversely, the probability of labor force withdrawal by the unemployed varies directly with the utility of nonmarket activity and inversely with the expected utility of search:

$$(5) \qquad P(UN) = d[\overset{(-)}{U(S)}, \overset{(+)}{U(N)}]$$

If we denote the probability of a job seeker getting an acceptable job in a month by $p$ and denote the utility of unemployed search by $C$, the expected utility of search can be expressed by:

$$(6) \qquad U(S) = pW + (1 - p)C$$

Substituting (1) and (6) into (4) and (5) gives us the following expressions for the labor force entry and withdrawal probabilities:

$$(7) \quad P(NL) = e\left[pW + (1 \overset{(+)}{-} p)C, \; b_0 + b_1 Y \overset{(-)}{+} \sum_i \alpha_i D_i\right]$$

$$(8) \quad P(UN) = d\left[pW + (1 \overset{(-)}{-} p)C, \; b_0 + b_1 Y \overset{(+)}{+} \sum_i \alpha_i D_i\right]$$

If the utility of unemployed search $(C)$ is constant, then the following are equivalent formulations for (7) and (8):

$$(9) \qquad P(NL) = e(D_1, \ldots, D_{11}, \overset{(+)}{pW}, \overset{(-)}{p}, \overset{(-)}{Y})$$

$$(10) \quad P(UN) = d(D_1, \ldots, D_{11}, \overset{(-)}{pW}, \overset{(+)}{p}, \overset{(+)}{Y})$$

## *Empirical Results*

In Tables 1 and 2 we report some regression results for white males and females in four age groups. We estimated linear functions corresponding to (3), (9), and (10). The transition probabilities $P(EN)$, $P(UN)$, $P(NL)$ were estimated for each group by taking the *CPS* monthly gross flow of persons changing from one state to another and dividing it by the number of persons in this state of origin in the previous month.[4] The monthly real wage was estimated by the *BLS* average hourly earnings of nonsupervisory personnel divided by the Consumer Price Index.[5] As a proxy for monthly family income, we used the monthly real wage multiplied by the employment of white prime-age males and divided by white population. The series on population was linearly interpolated from annual census data. This family income proxy captures the effect of job loss by prime age males on family income. Eleven monthly dummy variables were included to remove seasonal variation.[6]

The probability of job search success ($p$) was estimated from the disaggregated gross change data. In the entry function, $p$ was estimated by the ratio of the number of persons moving directly into employment from outside the labor force to the total number entering the labor force in any month. In the withdrawal from unemployment function the estimator was the ratio of the number of persons moving into employment from unemployment to the number of unemployed in the previous month.[7]

[4] Since we do not have information on whether job separations are voluntary quits or involuntary layoffs or dismissals, the transition probability $P(EN)$ is not a pure estimate of quits to leave the labor force. However, $P(EN)$ is likely to be dominated by voluntary job separations, since persons who experience involuntary job separations are very likely to be counted as unemployed rather than out of the labor force for at least two reasons. First, the unemployment insurance system creates an incentive for persons losing jobs to classify themselves as in the labor force since benefits are conditioned on job search activity. Second, the *CPS* counts as unemployed anyone on layoff from a job if he is available for work regardless of the extent of his job search activity.

[5] This is an aggregate wage rather than a demographically specific wage. Unfortunately, there is no monthly series on wages by demographic characteristics.

[6] The seasonal dummies were constrained so that the constant term is the average of the effects over all twelve months rather than the effect in a particular month.

[7] Although the probability of job search success ($p$) is conceptually the same in the entry and withdrawal functions, we decided to measure it differently to take advantage of the additional information available in the number of persons who are recent entrants into the labor force. Presumably, the entrance decision is affected more by the probability of job search success at initial entry than by the probability of success after having been unemployed for a while. In addition, new entrants may have different characteristics and face different opportunity costs. For example, new entrants are less likely to be collecting unemployment insurance.

TABLE 2—LABOR FORCE PARTICIPATION TRANSITIONS: WHITE MALES BY AGE

| Independent Variable | Quits to Leave the Labor Force: $P(EN)$ 16–19 | 20–24 | 25–59 | 60+ | Labor Force Dropouts by the Unemployed: $P(UN)$ 16–19 | 20–24 | 25–59 | 60+ | Labor Force Entrances: $P(NL)$ 16–19 | 20–24 | 25–59 | 60+ |

| $Y_{-1}$ | 0.76 | 0.18 | 0.04 | 0.83 | −0.10 | 0.88 | 1.01 | 2.51 | 0.41 | −0.47 | −1.23 | 0.07 |
| | (1.7) | (1.1) | (2.2) | (5.6) | (−0.7) | (0.9) | (1.8) | (2.1) | (0.6) | (−0.6) | (−2.6) | (0.7) |
| $p$ | | | | | 2.70 | 1.23 | 0.51 | 7.45 | −0.11 | −0.84 | −0.52 | 0.05 |
| | | | | | (1.3) | (1.0) | (0.6) | (2.7) | (0.2) | (−1.5) | (−1.6) | (0.8) |
| $R^2$(Corrected) | .94 | .89 | .37 | .64 | .53 | .01 | .32 | .07 | .96 | .95 | .38 | .38 |
| Durbin-Watson | 1.96 | 1.66 | 1.95 | 1.82 | 1.53 | 1.82 | 1.70 | 1.87 | 2.16 | 1.89 | 1.59 | 2.41 |

The tables contain the following data: the regression coefficients (except for those on the monthly dummies) with t-statistics in parenthesis, the $R^2$ corrected for degrees of freedom, and the Durbin-Watson statistic.

The model of labor force participation suggested above is strongly supported by the data. Of the coefficients on the economic variables, 58 of 64 have the predicted sign. In general the wage and income coefficients are larger for women than for men. This was expected since women have better nonmarket opportunities than men.[8]

### III. The Wage Change Process

We postulate that the rate of change of wages of a particular demographic group is determined by a group specific Phillips curve which gives a role to both wage change expectations and excess demand. Demographic stratification into. sixteen age-race-sex groups captures differences in skills, market opportunities, and the process of wage change which are correlated with demographic characteristics. Since we are considering wage determination within demographic groups, some attention must be given to the transmission of demand and supply across labor market sectors. The rate of wages for a particular group will be affected not only by excess demand in the group's labor market but by conditions in other labor markets as well. For example, if demand for white male labor is high, white male wages rise until it becomes profitable for employers to substitute other types of labor. This substitution process suggests that the rate of wage change in a particular sector is dependent on excess labor demand in all of the sectors. The magnitude of the response of wages in one sector to market conditions in other sectors depends on both the extent of substitution possibilities between types of labor and the relative attractiveness of the jobs in the other sectors. On the demand side, the lack of substitution possibilities among types of labor creates frictions which intensify inflationary wage pressures. On the supply side, labor tends to remain in the sectors with the most attractive jobs, thus creating frictions which limit the mobility of labor into the sectors with poor jobs. This also intensifies inflationary

[8] Because the model is linear and aggregate wages were used, some caution must be exercised in making inferences about the responsiveness of the transitions to demographic wages. Because the aggregate wage overstates female wages and understates male wages, one would expect the coefficient on the aggregate wage to overstate the effect of demographic wages for males and to understate it for females.

pressures. These considerations suggest that the cross-sector effects on wage change are greatest when labor is easily substitutable on the demand side and when jobs are comparable in desirability on the supply side.

The role of wage change expectations in the Phillips curve is based on the notion that employers set wages over a contract period. In setting wages, firms are influenced by both the expected change in the market wage over the contract period and market excess demand. In a multisector framework the rate of change in wages will depend on excess demands in each sector and the expected change in the market wage. If we denote the excess demand for labor in sector $k$ in the year t by $X_{kt}$, and the expected rate of wage change by $\overset{e}{w}_{kt}$, then the rate of wage change in that sector ($w_{kt}$) is determined by a relation such as:

$$(11) \qquad w_{kt} = \sum_j f_{kj}(X_{jt}) + \alpha_k \overset{e}{w}_{kt}$$

where $f_{kj}(X_{jt})$ is the function relating excess demand in sector $j$ to the rate of wage change in sector $k$.

If wage expectations are adaptive according to:

$$(12) \qquad \overset{e}{w}_{kt} = \lambda w_{kt-1} + (1-\lambda)\overset{e}{w}_{kt-1}$$

then it follows that

$$(13) \qquad \overset{e}{w}_{kt} = \frac{\lambda w_{kt-1}}{1-(1-\lambda)D}$$

where $D$ is a delay operator such that $D^n w_{kt} = w_{kt-n}$. Substituting (13) into (11) gives us:

$$(14) \quad w_{kt} = \sum_j f_{kj}(X_{jt}) + \frac{\alpha_k \lambda w_{kt-1}}{1-(1-\lambda)D}$$

which expands to:

$$(15) \quad \begin{aligned} w_{kt} &= \sum_j f_{kj}(X_{jt}) \\ &\quad - (1-\lambda)\sum_j f_{kj}(X_{jt-1}) \\ &\quad + (1-\lambda+\alpha\lambda)w_{kt-1} \end{aligned}$$

If instead of adaptive expectations we assume the expected rate of wage change is proportional to the wage change in the previous period

$$(16) \qquad \overset{e}{w}_{kt} = \lambda w_{kt-1}$$

we get the simpler model:

$$(17) \qquad w_{kt} = \sum_j f_{kj}(X_{jt}) + \alpha_k \lambda w_{kt-1}$$

### *Data and Empirical Results*

Our data analysis using models such as (15) and (17) is still in the exploratory stage. We have constructed an annual time series of earnings by age, race, and sex using both the March Current Population Survey and the Michigan Income Dynamics panel.The Michigan data were used only to derive the distribution of earnings across age groups within race-sex groups. These distributions were then imposed on the *CPS* earnings data for race-sex groups. Preliminary estimates using these data are not encouraging and are not reported here.[9]

## IV. In Conclusion

The dynamic labor force participation relations discussed in this paper are supported by data on short-term participation flows from the Current Population Survey. Our research on the impact of labor markets on relative wage rates is still in an exploratory stage and has yet to reveal any significant labor market effects. While we are unwilling to accept the conclusion that labor market conditions do not affect demographic wage rates, more research will be needed to determine the magnitude of these effects for different population groups.

The effect of wages and earnings on other transition probabilities needs to be

[9] The results are reported in Toikka, William J. Scanlon, and Holt.

explored, especially the quit relation. Since some structural policies affect worker and job availability and others, relative wages and prices, it is encouraging to see a structural model emerging that contains both allocators as a means of influencing workers and employers.

Research in the area of labor market dynamics is relevant for understanding the critical inflation-unemployment problem and policies for dealing with it. Allocation of more resources to basic research in labor markets and inflation will be necessary if we are to deal intelligently with the policy problems before us.

# On the Stability of the Racial Unemployment Differential

*By* ROBERT J. FLANAGAN*

During the post-World War II period, the simple ratio of black-white unemployment rates has shown remarkable stability at about 2:1, despite wide fluctuations in the rate of excess demand in labor markets. As a matter of arithmetic, this implies that recorded black unemployment changes twice as much as white unemployment in response to a given change in aggregate demand. In most discussions, the differential cyclical behavior of black and white unemployment is presumed to be associated with different exposure to layoffs and variously attributed to the tendency of blacks to have less seniority, to receive less specific training, and to be disproportionately employed in cyclically sensitive industries and occupations. Each of these is plausible, although evidence is generally offered only on the third.

While these "facts" may rationalize the observation that the black unemployment rate exceeds and is more cyclically sensitive than the white rate, they do not rationalize the *stability* of the relation until it is explained why the racial differences in job assignment, seniority, and specific training remain stable over time. A common response is that they reflect a stable intensity of discrimination over the period. But this merely restates the question, for there has been a substantial increase in the amount of private and public antidiscrimination activity since the early 1960's, and this should have had some impact on patterns of occupational assignment, seniority, and specific training of blacks.

The theme of this paper is that the stability of the aggregate racial unemployment ratio obscures important recent changes in the relative unemployment exposure of blacks in demographic subgroups defined by schooling, marital status, age, and labor force experience. Moreover, the key changes are most clearly revealed by separating unemployment experience over the life cycle (i.e., changes in unemployment associated with the aging or increased experience of a labor force cohort) from vintage effects (changes in the unemployment exposure of successive labor force cohorts) and by deemphasizing explanations based on racial differences in layoffs. The analysis of vintage and life-cycle changes in black relative unemployment also permits preliminary tests between competing explanations of racial unemployment differentials and changes in those differentials. In particular, it offers a solution to the puzzle of why the narrowing of racial earnings differentials in the late sixties was not accompanied by as dramatic and sustained a narrowing in unemployment differentials.

## I. Life Cycle and Vintage Hypotheses

### *A. Search Behavior*

Even in a color-blind labor market, unemployment would vary over the life cycle, for job search investments are rationally concentrated in early years of labor force

* Associate Professor, Graduate School of Business, Stanford University. Work on this paper was supported by contract no. L–74–131 from the Office of the Assistant Secretary for Policy Evaluation and Research in the U.S. Department of Labor. The paper does not necessarily represent the views of the Department of Labor, its agencies or staff.

experience. Moreover, the relative unemployment exposure of younger workers is further increased if the appropriate wage distribution is not known in advance and if there are systematic tendencies toward over-optimistic wage expectations among youth. Early periods of unemployment then serve to bring wage expectations into line with wage offers.

A racial unemployment differential can emerge if blacks expect to receive offers from the same wage distribution as whites but in fact face a lower distribution of wage offers. With labor force experience, the wage expectations of both races should become more accurate and their unemployment rates should decline. Moreover, as blacks learn that the distribution of wage offers differs by race, and their wage expectations adjust accordingly, search-motivated unemployment exposure of blacks and whites should become more similar. This important life-cycle implication of a converging race differential distinguishes the unemployment predictions associated with search behavior from some other explanations. In general, however, the convergence will stop short of equality of the black and white unemployment rates to the extent that a net racial wage differential persists, for this will tend to raise the quit rate and the time-intensity of search by blacks.

### *B. Labor Quality*

Measures of both the inputs (resources) and outputs (completion and achievement score levels) of the schooling system indicate that (1) the quality of each year of schooling is lower for blacks than whites and (2) the racial difference in school quality has been narrowing over time (Finis Welch 1973). In principle the school quality differentials could have both direct and indirect influences on racial unemployment differences.

To the extent that lower school quality affects job performance, workers who receive lower quality schooling may be systematically assigned to jobs which are relatively sensitive to seasonal and cyclical fluctuations and, in general, might accrue less seniority and protection from layoff. However, racial unemployment differentials which result from the *direct* effects of school quality differentials should be relatively *stable* over the life cycle after completion of schooling.

On the other hand, if relatively low school quality limits (or is believed to limit) an individual's ability to benefit from specific training, racial school quality differentials may have further indirect effects on unemployment. In particular, if specific training is a positive function of school quality, and if specific training accumulates with the aging (labor force experience) of a cohort, then racial differences in quits, layoffs, and associated unemployment exposure should *widen* over the life cycle as whites received relatively large specific training investments. Both the potential direct and indirect effects of racial school quality differences imply a life-cycle pattern of racial unemployment differentials that differs sharply from the narrowing life-cycle differentials implied by the search behavior explanation and which can be examined in the data below.

In contrast to the search behavior story, the labor quality explanation yields clear implications concerning vintage effects. If the *relative* quality of black schooling has been increasing over time, as evidence seems to indicate, the racial unemployment differential attributable to quality differences should be smaller in each successive cohort for a given length of labor force experience.

### *C. Declining Wage Discrimination*

Equal opportunity policies of the past decade have had two major elements, both of which should influence the pattern of

unemployment among blacks and whites. One objective, associated with affirmative action programs, has been to increase the relative employment and utilization of labor force minorities and in the case of blacks has apparently stimulated demand most for new cohorts of college graduates (see below). The other objective has been to achieve something approximating equal pay for equal work and has had a more complex impact.

Theories of discrimination based on aversion toward blacks or methods of screening workers of uncertain quality predict that institutional constraints on racial wage discrimination will tend to widen racial unemployment differentials. In the case of employer aversion, racial wage differentials compensate for prejudice; in the case of statistical discrimination, they compensate risk-averse (but unprejudiced) employers for risk when the testing process is less reliable for blacks than whites. With full wage compensation, theories predict no racial differences in the probabilities of layoff or hire. However, employers will adjust to equal pay for equal work laws and other constraints on wage discrimination by practicing discrimination in employment.

Nevertheless, these propositions can provide an erroneous guide to the interpretation of aggregate unemployment differentials for two reasons. First, accepting a lower wage does not empirically reduce the probability that a black will be laid off. Second, the racial wage difference tends to increase the relative quit rate and the time intensity of search among blacks. (For evidence, see Flanagan, 1975.) Therefore, the net effect of a reduction in racial wage discrimination should be to *reduce* racial unemployment differentials among *experienced* workers as black quits and the time intensity of black search fall.

The effect on experienced workers is stressed, because a fall in wage discrimination will raise the value of market relative to nonmarket activity for blacks and tend to increase the flow of black labor force entrants which will normally increase unemployment during the transition. The general relationship between changes in racial wage and unemployment differentials will depend on the relative magnitude of the offsetting unemployment adjustments among experienced and inexperienced workers. In large measure this will simply reflect the proportion of a particular age or experience cohort which is not in the labor force. Clearly the size of the potential entrant flow is largest in the youngest cohorts where the percent out of the labor force is relatively large. On the other hand, it is unlikely that unemployment associated with induced labor force entry would be sufficiently large to overwhelm the falling unemployment differential for experienced workers among prime-age males.

The vintage effects of falling wage discrimination are now clear. Each successive cohort of experienced workers should have a smaller racial unemployment differential. The vintage effect may be difficult to observe in the youngest cohorts because of the difficulty of isolating experienced and inexperienced workers in the data (except by age). Indeed, it is possible that racial differences may widen in groups dominated by inexperienced workers. An empirical analysis of these effects follows.

## II. Empirical Analysis

### *A. Life-Cycle Developments*

Table 1 is constructed to reveal changes in the relative unemployment of black males associated with aging ten years (1960–1970), after schooling, marital status and age cohort are held constant. For convenience, most of the discussion is focused on men who are married with

wife present. For the decade of the 1960's, the data show a substantial, across-the-board decline in the relative unemployment of blacks twenty-five years of age and over in 1970 (16+ in 1960). Moreover, the falling relative unemployment exposure of experienced blacks is observed in virtually all age cohorts, with the largest declines associated with the aging of the older cohorts, in which the unemployment ratio was greatest in 1960.

These data do not support the notion that racial differences in school quality and specific training were the dominant influence on life-cycle racial unemployment patterns for the period 1960–70. It is equally doubtful that search motivations are the sole explanation for the life-cycle decline in the relative unemployment of blacks. If search motivations were the dominant influence on racial unemployment patterns, one would expect that the life-cycle declines would be smaller in the older cohorts. Since the search explanation rests on the assumption that blacks *initially* fail to distinguish between the full market wage distribution (for a given skill) and the distribution of wage offers to blacks, racial unemployment differentials should converge most rapidly as blacks learn that the distributions differ. But this is a process which should be completed within a few years of labor force experience. At best, this pattern is observed only weakly in the data.

*Schooling.* In 1960, the racial unemployment ratio varied substantially by age cohort and schooling level. In general, the relative unemployment exposure of blacks was greatest at the highest schooling levels, where the black labor force share was disproportionately low. During the 1960's racial schooling differences continued to narrow, increasing the relative supply of blacks in higher schooling categories. In the absence of shifts in the relative demand for blacks or a fall in the

*Source:* see Table 1.

black relative wage, the increased relative schooling would have raised the relative unemployment of blacks as the black labor force grew most rapidly in schooling levels which had the highest unemployment exposure in 1960.

But in reviewing the data across schooling categories (see Table 2), it is clear that (1) declines in black relative unemployment are virtually across the board and (2) the largest declines over the decade are in the post-high school groups which recorded the highest relative unemployment in 1960. These declines therefore offset any opposite tendencies attributed to the shifting labor force composition of blacks toward higher schooling levels. By 1970 the unemployment rates of blacks and whites were near equality for those with eight years *and* for those with sixteen years of schooling.

Since the relative wage of highly-schooled blacks increased over the decade (see Richard Freeman, J. P. Smith and Welch), the data are consistent with the view that the employer response to changing demand and growing antidiscrimination activity has been to hire the most educated and the most recently graduated blacks first. For the cohorts over 25 years of age in 1960 (35 and over in 1970), an increase in the relative supply of schooling was generally not feasible. Given the inelastic supply of higher schooling in these age cohorts, increases in employer demand achieved substantial reductions in relative unemployment (and increased relative earnings). In younger cohorts, schooling was not necessarily complete in 1960, and individuals could therefore adjust their school-leaving plans in response to shifts in demand. The supply of labor with a given level of schooling should be more elastic in these cohorts, implying a somewhat smaller decline in relative unemployment (increase in relative annual earnings) if increases in demand were spread evenly over all cohorts. In fact, the largest decline in relative unemployment was for men aged 20–24 in 1960 who had completed 16 years of schooling by 1970. This suggests that increases in relative demand for black workers were greatest for recent college graduates.

TABLE 3—CHANGE IN RACIAL UNEMPLOYMENT RATE RATIO, 1960–70

| 25+ | −.45 | −.22 |

*Source:* see Table 1.

### *B. Vintage Effects*

The pattern of vintage effects is summarized in Table 3. The prevalence of negative signs indicates that in general the more recent black cohorts at each age have lower relative exposure to unemployment than a decade earlier. However, this generalization is somewhat qualified along the dimensions of labor force experience and marital status. The greatest narrowing of unemployment differentials occurred for more experienced cohorts (25 years and older) who had largely completed their schooling by 1960. Moreover, strong vintage reductions in racial unemployment differentials also occurred within schooling groups. (The vintage reductions in *relative* unemployment were largest for workers who were married with wife present. Because unemployment rates are generally lower in the "wife present" marital status category, however, the most extensive narrowing in racial unemployment *differences* occurred in the "other" category in which the racial differences were greatest at the beginning of the period.)

However, the vintage effects among in-

experienced workers are in the opposite direction. Over the decade, the racial unemployment differential increased in the 16–19 year group and was focused on the "other marital status" group, which comprises the majority of the labor force at this age.

This particular pattern of vintage effects is not fully consistent with the labor quality view, which does not explain why racial unemployment differences have declined for new vintages of experienced workers but increased among new vintages of teenage workers. As noted above, however, the pattern of vintage effects can be explained by a fall in wage discrimination and generally improving market opportunities for blacks. In age groups where the potential size of the induced flow is large (that is, groups with relatively low labor force participation rates), the tendency of racial unemployment differences to fall among experienced workers in response to greater equality of opportunity may be offset by rising unemployment among new labor force entrants. The crucial link in this behavioral explanation of the vintage effects is a rise among teenage blacks of unemployment associated with labor force entry.

This issue was pursued using quarterly *BLS* data on unemployment by reason, which have been available in reliable form only since 1968. For the period 1968–73, there was a trend increase in black (but not white) unemployment after adjustment for cyclical and seasonal influences. It was possible to decompose the black trend into the effects of trends in unemployment associated with layoffs, quits, labor force entry and reentry among adults and teenagers as well as changes in the demographic composition of the black labor force. The decomposition of the 1968–73 trends in the unemployment rates by source indicates that the main contributory factors were statistically significant secular increases in the new entrant rate among black teenagers of both sexes. (Unreported regression results are available from author.)

At the root of the "puzzle" of the stability of the aggregate racial unemployment ratio during a period in which other indicators of racial differences in economic status narrowed considerably is a failure to distinguish between the impact of antidiscrimination programs on experienced and inexperienced workers. Among groups with a high labor force participation rate, the dominant influence should be a narrowing of unemployment associated with quits and layoffs, and in fact the Census data show that race differentials have narrowed substantially among experienced workers. However, one effect of antidiscrimination programs can be to raise expectations of the level of market relative to nonmarket rewards. This will tend to raise the rate of gross labor force entry among groups in which many individuals previously opted for nonmarket activity. Youth is the most obvious example, and we observe that (1) the relative unemployment of black males with little work experience has increased while the relative unemployment of experienced black workers had declined, and (2) virtually all of the recent trend *increase* in the unemployment of teenage black males is associated with labor force entry. Alternative explanations, most notably the influence of minimum wage legislation, fail to account for why the trend increase appears to be restricted to black youth during a period in which racial quality differentials have narrowed substantially. Moreover, over the 1968–73 period, the ratio of the basic minimum wage to private nonfarm average hourly earnings (adjusted for coverage) declined, so that the influence of minimum wage legislation on general teenage unemployment should have dissipated.

# Occupational Mobility and the Distribution of Occupational Success Among Young Men

By Robert E. Hall and Richard A. Kasten*

Interpretation of the distribution of occupational success depends crucially on an understanding of the process of mobility. If the holders of low-paying jobs this year are just as likely as anyone else to hold good jobs next year, then the lower tail of the earnings distribution is not a matter of great social concern. Further, if the distribution of success is primarily determined by a random process, the prospects for a significant reduction in the inequality of earnings are unfavorable. On the other hand, high mobility in the short run may conceal systematic stratification of the labor force—it may be that the same individuals spend most of their time in the worst jobs. If so, luck and random events may play a small role in the distribution of well being, inequality may be a major issue, and the elimination of stratification may hold out the promise of an important reduction in inequality.

Simple tabulation of distributions of success and of mobility among categories of success cannot answer the basic question of the role of stratification. In this paper, we develop a model and statistical method for studying mobility and relating it to characteristics upon which stratification may be based. Our study rests on annual interviews conducted from 1966 through 1969 with about 3,000 white males born between 1942 and 1952.[1] We find that mobility is closely related to personal characteristics, especially intelligence and education. Men with high *IQ*s and extensive education are more likely to move to high-paying jobs and are more likely to remain in them. Nevertheless, random events dominate the distribution of occupational success in the short run. Our results strongly support the finding of Christopher Jencks and his collaborators that redistribution of the determinants of earnings would do almost nothing to reduce the observed inequality of annual earnings.

## I. The Model

Our concern is with the distribution of occupational success, not just with its expectation, so we are obligated to formulate a model that is explicitly probabilistic. Our first step is to make occupational success a discrete measure taking on only five alternative values (construction of the measure is described in the next section). The distribution of success is the fraction of the labor force in each of the five categories. The process of occupational mobility is portrayed within the model in a set of three probability distributions. The first is the simple binary probability that a worker will change jobs in a given month; this probability depends on his age, intelligence, and education. The second is the five-way distribution of the category of the new job for job-changers, which depends on personal characteristics and on the category of the previous job. The third probability applies to workers

* Dept. of Economics, Massachusetts Institute of Technology and the Dept. of Health, Education and Welfare, respectively.

[1] In this paper we concentrate on whites. In an earlier paper (see list of references), we studied black-white differences in the same framework.

who have remained on the same job for at least 12 months and gives the distribution among job categories as the result of promotion or demotion within the same firm. Again, this distribution depends on personal characteristics and on the previous occupational category. The model also treats education as an endogenous variable. Each year, there is a probability that an individual will return to school in September. This probability depends on personal characteristics, especially *IQ*, and is much higher for those individuals who were in school the previous year. For those who leave school and enter the labor market, there is a probability distribution for the occupational category of the first job. The five major probabilities of the model will be called the "change job," "new job," "promotion," "return to school," and "first job" equations.

The model is sufficiently general to encompass the two extreme views that mobility is a purely random process, on the one hand, and that stratification is absolute, on the other hand. Pure randomness would reveal itself as identical probability distributions for all individuals, independent of intelligence, family background, or other immutable characteristics. Absolute stratification would show up as probability distributions that made unambiguous predictions of different careers for differently endowed individuals, making the observed distribution of mobility entirely the result of the distribution of endowments. Between the two extremes, the more sensitive are the probabilities to the personal characteristics, the more evidence there is of stratification.[2]

## II. Data

Our data are taken from the National Longitudinal Survey of Work Experience (the Parnes data) for young men. From the annual surveys, we reconstructed a monthly chronology of activities of the members of the sample.[3] We created the five occupational categories by the following procedure. First we imputed earnings to each 3-digit occupation as the average annual earnings of individuals holding those occupations for 50 or more weeks in 1959. We then defined five categories, chosen so that our sample was roughly evenly distributed among them. These are

category 5: more than \$5900
category 4: \$5100 to \$5900
category 3: \$4600 to \$5100
category 2: \$3700 to \$4600
category 1: \$3700 or less.

After detailed study, we found this approach to occupational classification superior to its two main competitors: the Duncan-Blau socioeconomic score (*SES*),

[2] Econometrically, the dependence of the probability on personal characteristics and other determinants is indexed within our model by the parameters of a logit function:

$$p_i(x_t) = \frac{e^{x_t \beta^i}}{\sum_{j=1}^{N} e^{x_t \beta^j}}$$

$p_i\,(x_t)$ is the probability of the $i$th alternative, as follows:

change job:
$i=1$ no change
$i=2$ change
return to school:
$i=1$ return
$i=2$ enter labor market
new job, promotion, first job:
$i=1,\ldots,5$ for 5 occupational categories;

$x_t$ is a vector of immutable personal characteristics (family background and *IQ*), human capital (education and experience measured by time on the job) and market effects (captured by a set of dummy variables for years). Each alternative has a vector of parameters, $\beta^i$, which determine the influence of the variables, $x_t$, on the probability that $i$ will occur. We normalize the $\beta$s by setting the vector $\beta^1$ to zero, so each of the other $\beta^i$s controls the probability of the other alternatives relative to the probability of the first. In presenting the results, we focus on the $p_i$ values implied by our estimates of the $\beta$s rather than on the $\beta$s themselves. Estimation of the $\beta$s was carried out by conventional techniques of maximum likelihood.

[3] An appendix describing the data in more detail is available from the first author.

which attempts to take account of the nonmonetary rewards to occupations, and the actual earnings reported in the survey. The *SES* has a pronounced bias against blue-collar jobs which is particularly inappropriate for our sample. Actual earnings are reported for most but not all of the jobs held by members of the sample. However, among young workers, an important component of the return to labor in some jobs is the accumulation of training on the job (see Jacob Mincer). We concluded that the earnings of workers of all ages holding a given occupation is a better measure of the economic value of the occupation than is the reported wage of a young worker.

## III. Properties of the Individual Components of the Model

### *A. Education*

The typical young man remains in school until the end of the school year and then takes a job at the beginning of the summer. At the end of the summer he faces the central decision whether to remain at work full time or to return to school. The probability of returning to school is the determinant within our model of the amount of education received by each individual and is a function of *IQ*, family background, age, and grade last completed, as well as other variables of lesser importance. The combined influence of age and last grade make the model predict the appropriate distribution of total grades completed, especially the large fraction that completes exactly 12 grades. For the questions addressed by this paper, the important variables here are *IQ* and family background (measured by the father's *SES*). Both have the expected effect—more favorably endowed individuals tend to continue longer in school. *IQ* is the stronger of the two influences. Individuals who are 10 points above the average *IQ* of 100 have a 64 percent probability of going on to college after high school, against 53 percent if *IQ* is 100. By contrast, individuals whose fathers have *SES*s 32 points above the average of 36 have only a 59 percent probability of college, against the same 53 percent if *SES* is 36. The two variables have comparable effects at other stages in the educational process. Since education and the time of entrance into the labor market have profound effects on occupational success, the impact of these two variables on the decision to continue in school is a major stratifying influence.

### *B. First Job*

The occupation of the first job has a central role in our analysis. Some young men remain in their first job throughout the span of our study, and for those who do change occupations, the earlier occupation has a strong influence on the new occupation. The first job marks the transition between the accumulation of general human capital at school and the accumulation of occupation-specific human capital on the job. The latter process is one of the major explanations of the persistent effect of the early occupation on the subsequent career.

It is impossible to separate the effects of age and education on the first job, since at the time most men are six years older than the grade they complete. The combined influence of the two is dramatic and shows clearly that the process that assigns men to first jobs is far from random. High-school dropouts who enter the labor market at age 16 typically find poor jobs—44 percent in the lowest category and another 24 percent in the second category. Only 13 percent find first jobs in the top two categories. At the other extreme, college graduates entering at age 22 go overwhelmingly into the top of the occupational structure—58 percent into category 5 and another 19 percent into category 4.

Only 18 percent of them fall into the two lowest categories. High school graduates are between the two extremes, distributed by category as follows: 1. 33 percent, 2. 24 percent, 3. 17 percent, 4. 18 percent, and 5. 8 percent.

Apart from their indirect effects through education, intelligence and family background make roughly equal direct contributions to the level of the first occupation. For high school graduates, an individual with an *IQ* of 115 has a 30 percent probability of taking a job in category 1 and a 10 percent probability in category 5, against 33 percent and 8 percent respectively for those with the average *IQ* of 100. Individuals whose fathers have an *SES* of 68 had only a 26 percent probability in category 1 and 9 percent in category 5, against 33 percent and 8 percent for those whose fathers have the average *SES* of 36. Not surprisingly, having a well-placed father seems to help most in keeping the son out of the worst jobs.

### *C. Promotion*

In the Parnes data, occupation is reported annually for young men who do not change employers. About one-quarter of the workers change occupations, and of these, two-thirds are promotions (movements into higher occupational categories) and the rest demotions. For high school graduates with average endowments (*IQ* of 100 and father's *SES* of 36), the model implies the matrix among occupational categories shown in Table 1. Particularly noteworthy is the high probability of promotion out of the two lowest categories. Workers who are able to remain with the same employer move rapidly out of the worst jobs. The lower tail of the distribution of workers among occupational categories does not represent workers who are permanently trapped in poor jobs within the same firm. The mobility process for young workers has a pronounced upward bias; almost all the upper right-hand elements of the transition matrix are larger than the corresponding lower left-hand elements.

TABLE 1—MATRIX OF OCCUPATION CATEGORIES FOR HIGH SCHOOL GRADUATES WITH AVERAGE ENDOWMENTS WHO DO NOT CHANGE EMPLOYERS

| Category Last Year | Category this Year | | | | |
|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 |
| 1 | .50 | .18 | .16 | .08 | .07 |
| 2 | .02 | .65 | .09 | .15 | .09 |
| 3 | .01 | .07 | .73 | .11 | .08 |
| 4 | .00 | .08 | .07 | .76 | .08 |
| 5 | .02 | .06 | .07 | .12 | .73 |

Endowments and education have small but important influences on advancement within the firm. High-school graduates previously in category 3 have a 19 percent probability of promotion to categories 4 or 5, while the same probability for workers with two more years of education is 20 percent. A 15-point increment in *IQ* raises the probability for the high school graduate from 19 percent to 23 percent. Father's *SES* has no systematic effect on promotion or demotion. The effects of education and *IQ* cumulate year after year in the process as long as the worker remains with the same firm, so their long-run effects are much larger than is suggested by the small shifts in the transition matrix they induce.

### *D. Job Changes*

About 6 percent of the working members of our sample lose or leave their jobs each month (the data do not permit us to distinguish the two sources of changes). Virtually all of them find new jobs within a month or two, often with an intervening spell of unemployment. The rate of turnover is an important determinant of the dispersion of occupational success, as

TABLE 2—MATRIX OF OCCUPATION CATEGORIES FOR HIGH SCHOOL GRADUATES WITH AVERAGE ENDOWMENTS WHO CHANGE JOBS

| Category of Old Job | Category of New Job | | | | |
|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 |
| 1 | .19 | .26 | .21 | .21 | .13 |
| 2 | .07 | .46 | .14 | .22 | .11 |
| 3 | .06 | .18 | .47 | .18 | .11 |
| 4 | .05 | .17 | .16 | .52 | .09 |
| 5 | .06 | .20 | .14 | .18 | .43 |

large upward and downward occupational movements are much more likely to occur when workers move between employers. Endowments and education seem to have almost no direct effect on the turnover rate. Turnover is highest among young workers, falling from 9 percent per month at age 16 to 4 percent per month at age 24. Workers are much more likely to leave or lose jobs in the lowest category (8 percent per month) than in the highest category (5 percent per month); the percent falls smoothly between the two.

### E. *New Jobs*

Most job changers improve their occupational category, or at least remain in the same category. The transition matrix for changers is shown in Table 2. Again, it is noteworthy that few workers remain in the worst jobs—those in the lowest category have both the highest probability of changing jobs and the highest probability of moving upward as a result of the change. The general bias of mobility through job changes is upward, but not as strongly as in the case of movements within the firm. Movements through the labor market are clearly riskier than movements within the firm.

Endowments and education have substantially more effect on the distribution of job changers among occupational categories than in the promotion equation. A high-school graduate has a probability of 20 percent of advancing from a category 3 job to categories 4 or 5, but this probability rises to 36 percent for an otherwise identical worker with 14 years of education. Fifteen extra points of *IQ* raises the same probability from 29 percent to 33 percent, and 32 extra points of father's *SES* raises it from 29 percent to 31 percent. Since job changes frequently involve dissipation of occupation- and firm-specific human capital, it is not surprising that the general determinants of success matter more in this equation and the category of the previous job matters less, relative to the promotion equation.

## IV. Properties of the Complete Model

When the probabilities described in the previous section are permitted to interact with one another, they imply a distribution of individuals across occupational categories at any given time. Within a group that is homogeneous with respect to

TABLE 3—DISTRIBUTION AMONG JOB CATEGORIES BY IQ, FATHER'S *SES* AND EDUCATION

| | Job Category | | | | |
|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 |
| *IQ* (full effects) | | | | | |
| 90 | .11 | .14 | .22 | .26 | .28 |
| 100 | .10 | .13 | .17 | .25 | .35 |
| 110 | .10 | .11 | .13 | .25 | .42 |
| *IQ* (holding grades at 12) | | | | | |
| 100 | .11 | .14 | .18 | .27 | .29 |
| 110 | .10 | .14 | .15 | .28 | .33 |
| Father's *SES* (full effects) | | | | | |
| 16 | .13 | .13 | .18 | .27 | .30 |
| 36 | .10 | .13 | .17 | .25 | .35 |
| 60 | .08 | .12 | .18 | .22 | .41 |
| Grades completed | | | | | |
| 10 | .11 | .15 | .24 | .30 | .20 |
| 12 | .11 | .14 | .18 | .27 | .29 |
| 14 | .10 | .12 | .14 | .21 | .43 |

the fundamental determinants of success (*IQ* and family background), those who are in the lowest category are the victims of an unfavorable random event. Some have just passed through the labor market and have taken a poor job; if they remain with their new employers, they are likely to move to better jobs fairly soon. Others may have left school unexpectedly early, in which case the model predicts that they are more likely to remain in the lower categories throughout their careers. The distributions of workers among categories induced by the complete model are shown in Table 3. The first three rows, labeled "*IQ* (full effects)," shows the distribution among occupations of a group of 24 year old men whose fathers all had the average *SES*, 36. All three distributions have a great deal of dispersion. Both the short-run randomness embodied in the mobility equations of the model and the long-run randomness in the educational process contribute to this dispersion. Bright individuals are almost as likely to be found in the worst jobs as a result of bad luck as are those with below average intelligence. On the other hand, a higher *IQ* substantially improves a worker's chances of landing a top job. Underlying the randomness in the assignment of workers to occupations is an important tendency favoring the more intelligent.

The next two rows of Table 3 show that most of the systematic effect of *IQ* operates through the educational process. When the probability distribution is computed conditional on exactly 12 years of school, the upward shift in the distribution for brighter individuals is much weaker. The next part of the table shows the full effects of family background, measured by the father's *SES*. The sons of well-placed fathers are at a substantial advantage in the labor market, though they are subject to the same random processes as everyone else. They are both less likely to be at the bottom of the occupational structure (this is the influence of the first job equation) and more likely to be at the top, when compared to otherwise identical men with less successful fathers. Finally, the last three rows of Table 3 show the major role of education in stratification at the upper occupational levels. Within the group of workers with average *IQ* and father's *SES*, those who obtain more education are much more likely to be in the best jobs. However, well-educated men face almost the same probability of holding the worst kind of job as do high school dropouts.

Table 4—Estimated Effects of Redistributing Individual Characteristics on the Distribution Among Job Categories

| | Job Categories | | | | |
|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 |
| Characteristics distributed as in sample | .12 | .13 | .18 | .22 | .35 |
| *IQ* held constant at 100 | .11 | .14 | .16 | .26 | .33 |
| Father's *SES* held constant at 36 | .10 | .13 | .18 | .22 | .37 |
| Grades completed held constant at 12 | .11 | .14 | .20 | .24 | .31 |
| All three held constant | .11 | .14 | .18 | .27 | .29 |

Table 3 shows that the determinants of occupational success matter a great deal. Men with high *IQ*s, with successful fathers, and with college educations are very clearly separated from those with less favorable backgrounds by their much higher probability of holding top jobs. The hypothesis that the underlying determinants of success are unimportant compared to the random influences is refuted by these results. Nonetheless, it is true that redistribution of the determinants of success would do almost nothing to reduce the unequal distribution of success. This controversial proposition, which has been advocated by Christopher Jencks

and his associates, is illustrated in Table 4.[4] In the first line, we show the distribution of the members of the sample predicted by the model, using the actual dates of birth, *IQ*s, and fathers' *SES*s (this distribution matches the actual distribution of the sample quite closely). In the second line, we show the hypothetical distribution within the sample if all its members had the average *IQ*. The next two rows repeat the exercise for father's *SES* and years of education separately, and the last line considers the result of making the sample homogeneous with respect to all characteristics except age. In all cases the results are striking. The model predicts that 25 percent of the sample will hold jobs in the two lowest categories. The only redistributional experiment that reduces this figure at all is the one that makes fathers' *SES* uniform. The only noticeable impact of redistribution is to shift workers from the fifth to the fourth categories.

[4] Our model describes the labor market only from the point of view of the worker, and does not deal with changes in wages caused by changes in supply. Our results on the impact of redistribution of endowments are strictly applicable only if the job categories are close substitutes on the demand side. Any lack of substitutability among the categories would make the impact of redistribution even smaller. Our results give an upper bound to the potential effect of redistribution.

Our findings can be summarized in two simple propositions:

(1) Intelligence, family background, and education matter a great deal. The occupational success of the entire labor force could be improved materially by increasing its endowments of any or all of the three.

(2) Redistribution of endowments would have almost no effect on the distribution of success. The favorable effects for the fraction of the labor force with below-average endowments would be largely offset by the unfavorable effects on those above the average.

# The Entrepreneurship Decision and Black Economic Development

*By* William D. Bradford and Alfred E. Osborne, Jr.*

In the last few years there have been tremendous efforts by various government agencies to promote minority entrepreneurship. These programs, the most notable of which was President Nixon's "Operation Mainstream," were intended to aid the process of black economic development through increased minority business formation. Most programs, however, appeared to simply encourage employed blacks to discontinue their salaried or wage occupation and attempt to become independent businessmen.

The extent to which black entrepreneurs can be mobilized to economically develop the community is not clear. If by economic development one primarily refers to sustained increases in per capita income of a given community and accepts that as the relevant definition,[1] it is important to understand how a policy which encourages primarily salaried individuals to become entrepreneurs might affect the relative standard of living in minority communities. This paper explores some basic propositions implied by such decisions.

## I. The Entrepreneurship Decision

The entrepreneurship decision can be considered a specific case of the many occupational choices available to an individual. Self-employment, however, has not received the attention given wage and salaried employment. The intensive analysis recently given the relationship between income, education, and occupational choice has virtually neglected those decisions which might result in a supply of entrepreneurs.[2]

While there are a few studies available which report on returns to the entrepreneurial sector, most are old, inconclusive, and often based on poor data.[3] Lauritis R. Christensen, however, reports that entrepreneurial labor and capital earn a rate of return approximately equal to that earned by corporate factors. These results are contrary to previous studies which report that entrepreneurial returns are smaller. While much more work needs to be done in estimating returns, the recent work does suggest that self-employment is a competitive alternative to business employment even though as a percent of national income entrepreneurial activities are on the decline.

Osborne (1975) has characterized the entrepreneurship decision as involving the choice between two income streams. In that paper a rational individual was assumed either (1) to accept (continue in) a wage position earning a certain amount of dollars per year or (2) to go into business with the anticipation of realizing

[3] Previous studies include Stanley Lebergott and D. Gale Johnson among others.

some share of the economic profits. It was formally shown that if T is the projected length of business involvement and $Y_t$ the yearly wage to be foregone, then the decision point comparison of total returns from business activity consisting of periodic withdrawals and other payments ($R_t$) plus terminal value ($V_T$) to employment can be expressed as[4]

$$(1) \qquad \sum_{t=0}^{T} \frac{Y_t}{(1+r_t)^t} \leq \sum_{t=0}^{T} \frac{R_t}{(1+\rho_t)^t} + \frac{\chi \cdot V_T}{(1+\rho_T)^T}$$

*where* $\chi$ is his share of the terminal equity value of the firm ($0 < \chi \leq 1$), $r_t$ is the rate at which wage or labor income is discounted and $\rho_t$ is the rate at which income from business activities is discounted in period t. For convenience, we will assume throughout our analysis that $\chi = 1$. This amount of wage income (in present value terms) would be willingly exchanged for entrepreneural income if the latter income stream is greater. A potential entrepreneur, black or white, is therefore assumed to base his decision on $V_T$, $Y_t$, $R_t$, $\rho$, $r$, and $T$. Further, any such entrepreneur is indifferent if only the weak equality condition in equation (1) holds.

Let us consider two representative entrepreneurs, one black ($B$) and one white ($W$). Define the left-hand side of equation (1) as $\hat{Y}_W$ and $\hat{Y}_B$; the two terms on the right-hand side as $\hat{R}_W + \hat{V}_W$ and $\hat{R}_B + \hat{V}_B$ such that

$$(2) \qquad \hat{Y}_B \leq \hat{R}_B + \hat{V}_B \quad \text{and} \quad \hat{Y}_W \leq \hat{R}_W + \hat{V}_W$$

[4] The value of human capital in period $T$, which will be positive under either alternative, is not herein analyzed. First, if $T$ is large, then the value of human capital will be small. Secondly, since the theory has not yet resolved the issue of the relative value of employment and entrepreneurship human capital (see Christensen, pp. 584–85), a simplifying assumption is that employment and entrepreneurship human capital in period $T$ are equal, and thus cancel each other out. In addition, external effects and nonpecuniary reasons for making this choice are not directly considered.

We can also extend the model to consider investment capital inputs (equity) by entrepreneurs which represent a portion of their accumulated wealth or savings. If $W_B$ *and* $W_W$ represent the initial capital input of a black and white entrepreneur respectively, expression (2) becomes

$$(3) \qquad \hat{Y}_B + W_B \leq \hat{R}_B + \hat{V}_B \quad \text{and} \quad \hat{Y}_W + W_W \leq \hat{R}_W + \hat{V}_W.$$

As before, equilibrium conditions in the employment and entrepreneurial markets exist only when the equalities in (3) hold.

## II. Entrepreneurs and Comparative Economic Welfare

Government programs to improve the standard of living for minority communities are typically judged on their impact on a variety of policy targets. The major target used in evaluating comparative welfare is the black/white income ratio (*BWIR*) defined as

$$(4) \qquad BWIR = \bar{Y}_B / \bar{Y}_W$$

where $\bar{Y}_B$ and $\bar{Y}_W$ are population mean incomes for the two groups.[5] Studies have shown that the *BWIR* is less than one and about .60.[6]

Concern on the part of policy makers with increasing the *BWIR* has led to a variety of programs including programs to promote minority entrepreneurship. Accepting the *BWIR* as the relevant measure of comparative economic welfare, we will now consider the entrepreneurial decision and changes in the *BWIR*. For ease in exposition we make the following definitions and assumptions.

[5] See James Gwartney, p. 872. This measure assumes that for any relevant geographical region in which there are $N$ and $M$ black and white individuals the ratio of means (or median income in the case of skewness) is, given that the standard deviation is identical for both income distributions, an adequate representation of relative economic well-being.

[6] Gwartney, pp. 873–74.

DEFINITIONS:

1. $\beta = W_B/W_W$
2. $\delta_i = W_i/(\hat{R}_i + \hat{V}_i), \qquad i = B, W$
3. $\Phi_t = Y_t^W/Y_t^B - 1$
4. $\theta_{ti} = R_{ti}/Y_{ti}, \qquad i = B, W$
5. $\alpha_t = (1 + r_t)/(1 + \rho_t)$

ASSUMPTIONS:

1. Consider a black and white worker of equal training and abilities. Because of labor market discrimination, $\beta < 1$ and $\Phi > 0$ for all t.

2. (a) Capital market restrictions are such that shifts from employment to entrepreneurship are allowed only if the prospective entrepreneur qualifies with some minimum value of $\delta(0 < \delta \leq 1)$, and (b) workers shift from employment to entrepreneurship at the maximum business values attainable, subject to capital market restrictions on $\delta$.

3. $\theta_t$ and $\alpha_t$ are constant for all t and their values will be expressed as $\theta$ and $\alpha$ respectively.

4. Homogeneous expectations and complete capital markets prevail.

*Proposition 1.* Consider a black worker and white worker of equal business training and ability. Because of discrimination in the labor market, the black worker can shift into entrepreneurship only at a smaller business value than that which is available to his white counterpart.

*Proof.* Define $f$ as the minimum value of $\delta$ required in the capital markets. Then $\hat{R}_W^* + \hat{V}_W^* = W_W/f$ and $\hat{R}_B^* + \hat{V}_B^* = W_B/f$ are the business values of each worker after shifting into entrepreneurship. Since $W_W > W_B$, then $\hat{R}_W^* + \hat{V}_W^* > \hat{R}_B^* + \hat{V}_B^*$, which completes the proof. The significance of proposition 1 is that even in the absence of ethnic discrimination in the capital markets a black cannot attain, on average, business value parity with a white of the same ability. An important reason is that financing institutions, such as banks, Small Business Investment Companies, require a minimum amount of equity capital to support a given size business. Earlier black capitalism programs *lowered* required equity values which resulted in adverse effects on the financing institutions as well as high default and business failures among minority entrepreneurs.[7]

*Proposition 2.* As black workers shift into entrepreneurship, the *BWIR* will increase, decrease, or remain the same depending upon the expected value of the firm, how this value is distributed across time, the magnitude of investment equity, and the relative size of $r_t$ and $\rho_t$.

*Proof.* The relationship between entrepreneurial income and employment income after a shift from employment to entrepreneurship can be expressed as

$$(5) \qquad \hat{R}_B + \hat{V}_B = \hat{Y}_B + W_B + \hat{C}$$

for the black worker, where $\hat{C}$ is some nonnegative present value. Dividing both sides by $\hat{Y}_B$ and simplifying with definitions 4 and 5 yields

$$(6) \qquad \sum_{t=0}^{T} \theta\alpha^t = 1 + \frac{W_B - \hat{V}_B + \hat{C}}{\hat{Y}_B}$$

It follows that

$$(7) \qquad \theta = \frac{1}{\sum_{t=0}^{T} \alpha^t} + \frac{W_B - \hat{V}_B + \hat{C}}{\hat{Y}_B \sum_{t=0}^{T} \alpha^t}$$

If $\theta = 1$, the *BWIR* remains the same; if $\theta > 1$, the *BWIR* increases, and if $\theta < 1$, the *BWIR* falls, which completes the proof.

The practical interpretation of proposition 2 is that the *BWIR* may *decrease* as blacks move from labor to entrepreneurial activities, even when there is a large in-

[7] See Bradford and Timothy Bates for an examination of this issue. A discussion of the magnitude of individual welfare losses from a Minority Enterprise Small Business Investment Company portfolio is found in Osborne.

crease in the present value of income ($\hat{C}$) when this shift is made. Three relationships are evident in the proof of proposition 2. When a shift is made by a black worker into the entrepreneurial position: (1) the higher the discount rate on entrepreneurial activity relative to the employment discount rate, the higher the positive change in the *BWIR*, (2) the larger the value of initial entrepreneurial wealth the higher the change in the *BWIR*, and (3) the higher the terminal value of the firm the lower the change in the *BWIR*, *ceteris paribus*. This final relationship is important in that a direct goal of governmental minority business programs is to encourage black business firms of higher present value ($\hat{V}_B$). As more emphasis is placed on viable businesses, withdrawals ($\hat{R}_B$) decrease, more funds are reinvested in the firm, and the *BWIR* falls.

Other relationships can be derived from the basic propositions. For example, if we assume "reverse discrimination" in some employment market (e.g., token blacks) such that $\hat{V}_B + W_B > \hat{V}_W + W_W$, then results opposite to proposition 1 hold. Such blacks can attain larger business values than whites of equal abilities and training.

Policy makers are no doubt concerned with the employment potential of business activity more than with the individual effects from one worker turned entrepreneur demonstrated in this paper. That extension to this model would recognize the possible multiplier effects of encouraging black entrepreneurs to hire marginal or unemployed black factors. As others have shown, this is not likely to occur if development is skill intensive.[8] Nevertheless, these are important issues which can also be developed beyond the basic framework briefly considered here.

[8] See Bates and Osborne on this point.

# Influences on Investment by Blacks in Higher Education

By WALTER W. MCMAHON*

There has been a significant improvement in the job markets for college educated blacks in the last 10 years, greater than the gains experienced by those who have not gone to college. National managerial job markets have opened up to blacks for the first time as evidenced by the major corporations recruiting blacks at the black colleges and by the increased number of governmental units and graduate schools seeking black graduates.

The additional years of college education are increasing black earnings but, even more important, are narrowing the earning gap between blacks and white. Median earnings of all blacks increased from 70 percent of median white earnings in 1967 to 81 percent of white earnings by 1974. The median earnings of black college graduates increased even farther to 94.7 percent of the earnings of white college graduates. (See T. F. Bradshaw 1975, p. 28.) This advantage of college training continued through the recession since unemployment rates in 1975 were 39–43 percent among those younger blacks with 8 years of education or some high school but only 3.3 percent among those blacks who finished college and had been in the labor force for two years. (See U.S. Bureau of Labor Statistics 1975, p. 5.)

This paper will present for the first time *ex ante* rates of return based on the earnings expected by individual black college students. Blacks and females are found to have unusually high expected rates of return, offering one reason for the increase in enrollments by blacks and females from 1970 through the 1975 recession. But since black and especially black male enrollments still remain disproportionately low, the access by black males to the newly open national managerial job markets remains limited by the influences that limit black enrollment in *U.S.* colleges. The second objective of this paper, therefore, will be to attempt to isolate the other major influences on the total amount of investment in college planned by blacks, and especially by black males. These influences, when compared to the investment behavior of white students and their families, can be useful in equalizing college enrollment persistence, and thereby access to the new job market opportunities that now await college educated blacks.

## I. Influences on Investment

The data consist of a nationwide sample of 7,019 prospective students and their families drawn in two waves in 1972 and 1973 in such a way that approximately half could have finished bachelor degrees in June 1975 and half in June 1976.[1] Blacks were deliberately oversampled to permit separate analysis of their behavior. The sample has been reweighted to conform to the distribution of all students with respect to sex, type of institution, and the

[1] Questionnaires and further details of the survey are published in McMahon, pp. 167–79 and p. 23.

proportion receiving financial aid, as given by a census of all students.

### *A. Ex Ante Private Rates of Return*

The *ex ante* private rate of return was calculated for each student in the sample based on the earnings each student said he expected to receive at graduation and to earn 25 years later. Age-earnings curves of the shapes given by Hanoch then were fitted to the two points for each student before earnings at each age based on only a high school education were deducted. The resulting stream of net expected additions to earnings was set equal to the family's actual net tuition, foregone earnings, and other investment costs, and the internal rate of return was calculated.

It was found that blacks expect very high ex ante rates of return, ranging from 20 to 40 percent, and that the *ex ante* rates of return expected by white females were the next highest (see Table 1). Consistent with the hypothesis that investment decisions respond positively to high rates of return, enrollment by blacks grew the most rapidly nationwide in this period with black enrollments increasing from 7 percent of all college students in 1970 to 9 percent in 1974. (See U.S. Bureau of the Census 1975, No. 279, p. 10.) Relatively few black males were enrolled to begin with, and since black male enrollment has grown to only 8.6 percent of all college age males, with blacks constituting 12 percent of the college age population (U.S. Bureau of the Census, p. 15), black males remain significantly underrepresented.

The continuing underrepresentation of black males is also evidenced by the fact that only 26 percent of all black male high school seniors were planning to attend college last fall, in contrast to the much higher 41 percent of all white male high school seniors that were planning to attend. (See U.S. Bureau of the Census 1975, No. 284, p. 10.) So although high expected returns have induced increased enrollment of black males, their enrollment has started from modest levels, and other factors limit the amount of investment in education they plan to make. These in turn become the main remaining barriers to full access to national managerial job markets.

TABLE 1—EXPECTED RATES OF RETURN AND ENROLLMENT

| Those Enrolled in *BA, BS* Programs | *Ex-Ante* Private Monetary Rate of Return | | Percent Increase in Enrollment, 1970–74 |
|---|---|---|---|
| | 1975 Graduates | 1976 Graduates | |
| Black male | 37.6% | 19.2% | 66.8% |
| Black female | 31.7 | 40.5 | 45.7 |
| White male | 21.5 | 11.0 | 7.4 |
| White female | 24.2 | 32.6 | 26.7 |

### *B. Factors Limiting Black's Investment Plans*

To isolate some of the other influences on the investment decisions made by black students and their families, a two equation model composed of an investment-demand (or marginal efficiency of investment) function and a supply-of-resources function was estimated using this microeconomic survey data by three stage least squares simultaneous equation methods. The model was estimated separately for black females, black males, white females, white males, and for all families in the lower income quartile (see Table 2).

The first result found is that although high expected rates of return ($r$) have encouraged black enrollments, the marginal efficiency of investment schedule does slope downward for black and for other population segments as expected, indicating that longer and more costly planned degree programs yield lower rates of return. (The coefficient of $r$ is negative and significant in Equations (1), (3),

TABLE 2—INFLUENCES ON THE AMOUNT OF INVESTMENT PLANNED IN HIGHER EDUCATION

| | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | | | *Black Females* (June 1976 B.A.s) | | | | | |
| *Total family investment, black females:* | | | | | | | | | |

| *Parents contribution only, black females:* | | | | | | | | | |
| (7) Demand ($MEI$): | $I_F=$ | $.67\,r$ | $+1.34\,\mu$ | $+.07\,A$ | $-.04\,S_p$ | $-37.5\alpha_c$ | $+4.76$ | | |
| | [a] | $(.27)$ | $(1.02)$ | $(1.32)$ | $(-.84)$ | $(-1.85)$ | $(1.56)$ | | |
| (8) Supply-of-resources: | $I_F=$ | $-.26\,r$ | $\underline{+.13\,Y}$ | $+.17\,S$ | $\underline{-.18\,L}$ | $\underline{-.08\,W}$ | $\underline{-.23\,N}$ | $\underline{-.42\,Y_o}$ | $\underline{+3.88}$ |
| | | $(-.79)$ | $(6.22)$ | $(.88)$ | $(-6.59)$ | $(-3.14)$ | $(-7.37)$ | $(6.20)$ | $(16.05)$ |
| | | | | *Lowest Income Quartile* (All Races, June 1975 B.A.s) | | | | | |
| *Total family investment, blacks and whites, males and females:* | | | | | | | | | |
| (9) Demand ($MEI$): | $I_F=$ | $\underline{-.32\,r}$ | $-.08\,\mu$ | $\underline{-6.36\,\text{Race}}$ | $\underline{-3.43\,\text{Sex}}$ | $+.23\,A$ | $-.13\,S_p$ | $\underline{+28}$ | |
| | [a] | $(-6.38)$ | $(-.03)$ | $(-3.08)$ | $(-2.32)$ | $(1.48)$ | $(-1.03)$ | $(5.72)$ | |
| (10) Supply-of-resources: | $I_F=$ | $\underline{-.015\,r}$ | $\underline{-.27\,Y}$ | $\underline{+.61\,L}$ | $\underline{-.34\,S'}$ | $\underline{-5.68\,W}$ | $-.07\,N$ | $\underline{+11}$ | |
| | | $(-4.01)$ | $(-3.46)$ | $(10.93)$ | $(-2.84)$ | $(-22.27)$ | $(-1.02)$ | $(25.63)$ | |

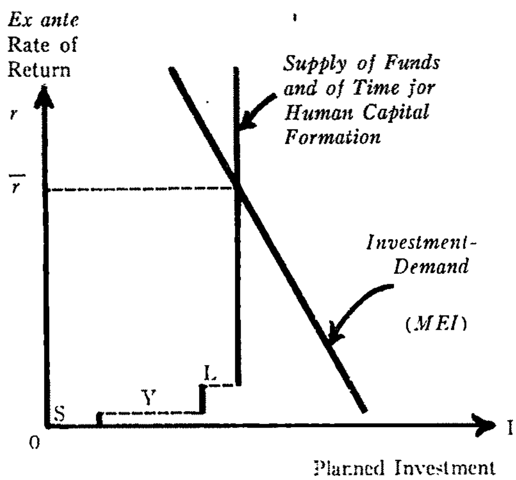
*Note*—investment demand ($MEI$) and supply-of-funds coefficients were estimated simultaneously for each population segment by three stage least squares. Respondents could have finished $BA$'s in June 1975 or June 1976. Coefficients significant at the .05 level are underlined, and $t$-statistics are in parentheses.

[a] For three stage least squares estimation, $\hat{I}$ is moved to the left in each supply equation.

$\alpha_c$ = A taste parameter reflecting the importance of college as an aid in making a choice of a career. Other variables are defined in the text.

(5), and (9), which is reflected in the negative slope of the investment-demand function in Figure 1.)

Second, uncertainty about future earnings ($\mu$) which might be expected to curtail student investment plans does limit the amount of investment planned by white males (5) and black females (1), but less significantly by black males (3). But third, higher ability ($A$) as measured by the American College Testing Service ($ACT$) achievement test scores clearly is a significant determinant encouraging most whites and black females to make more ambitious plans as predicted by economic theory. Ability is a less significant factor for black males, perhaps because black families more commonly expect males to go to work after high school. For black males, the number of years of schooling of the parents ($S_p$) however is is a uniquely significant positive determinant (in 3) of whether black males plan to go further in college.



I = Tuition and fees, books, and foregone earnings through planned degrees.

FIGURE 1. INVESTMENT DECISIONS MADE BY BLACK FAMILIES

It is on the supply-of-resources side that most of the highly significant effects on the size of the investment planned by black families are to be found. The most significant positive effects are from scholarships ($S$) and student loans ($L$) supporting larger student investment plans in (2), (4), and (6). The second largest positive effect is from family disposable income ($Y$), especially for females in (2) and (8). This significance of family income and related alternative sources of financial support is consistent with other studies using both microeconomic and time series data that also normally find income sources to be fundamental (e.g., McMahon 1974). A third significant factor on the supply side is part-time work ($W$) which by reducing the amount of time blacks (and others) invest in study is associated with persistence but with lower total planned investment.

In all the regressions tried, loans reduce the *parental* contribution in both black (8) and white families, but they increase the amount of investment planned by the student so that the net effect on total family investment is positive. See (2) and (4). A larger number of siblings in the family ($N$) clearly curtails the parents' contribution (8) which limits the resources available and significantly curtails the amount of parental support for both black and white females, as might be expected.

In summary, the most significant influences on college investment plans made by black males on the demand side are the newly held expectations of high rates of return ($r$) and tastes acquired from parents who have been to college ($S_p$). Improvements in the quality of primary and secondary education for blacks may also do much to improve ability test scores ($A$). But access to the occupations where the rates of return are highest such as business management, medicine, pharmacy, engineering, and law requires years in college. And investment in college by black males especially continues to be restricted by their primary and secondary school backgrounds ($A$) and by more limited sources of funds from parents—$Y$ in (4) and (10)—who themselves have not been to college.

With the improvements in the last decade in the opportunities available to college educated blacks, these influences become very significant factors limiting access by black males to the national managerial job markets.

# Some Alternatives for Reducing the Black-White Unemployment Rate Differential

*By* Karl D. Gregory*

Economic development involves promoting higher standards of living in part through generating saving for adding to the capital stock and productive potential of a community. Saving is a function of income. Most income is obtained from wages and salaries. It is therefore quite appropriate that this American Economic Association-National Economic Association session on "Trend and Analysis in Black Economic Development" include a paper on recent changes in the work status of blacks. Such a focus has been made more timely by the recent recession during which unemployment rates peaked at 8.9 percent in 1975–II, and for blacks, at 14.3 percent. Making matters worse, this was accompanied by a rate of inflation in the recession, the deepest of all since the Great Depression, which rose to double digit levels in 1974 and was over 7 percent in 1975.

Measurement of the unequal work status among blacks and whites in the United States involves, among other factors, differences in labor force participation rates, unemployment rates, discouraged worker rates, underemployment rates, working conditions, and levels of wages, fringe benefits and other compensation. This paper discusses primarily only one attribute of work status, unemployment, despite the incompleteness of this concept. (Other research in which I am currently engaged, along with associates in the Congressional Budget Office, will analyze the other attributes.) The paper summarizes the recent behavior of the black-white unemployment differential, reviews the likely impact on the differential of two recovery paths, one for moderate recovery and another for rapid recovery by 1978–IV, and briefly suggests some alternative selective programs for narrowing the black-white differential in a short time period. I shall try to share with you some of the tentative and preliminary conclusions on these matters produced by ongoing research at the Congressional Budget Office.

## I. Unemployment and the Black-White Differential, Recent Experience

The extent to which the black unemployment rate exceeds that for whites (hereafter referred to as the gap) varies greatly over the business cycle. For the last 20 years this gap has ranged from 2.9 percentage points in 1969 to 6.8 percentage points in 1958. Not surprisingly, it is lowest at the end of an extended economic ex-

* Visiting Scholar, Congressional Budget Office (*CBO*), and Professor of Economics and Management, Oakland University. The author is indebted to colleagues at *CBO* with whom he has been conducting studies on reducing differences in the status of blacks and whites in the United States. He alone is responsible for any errors. Charts depicting relationships discussed in the text are available from the author. Two publications by *CBO* discuss the subject more extensively: "The Impact of Economic Recovery on Unemployed Nonwhite and White Americans: A Preliminary Assessment," (mimeo) and *Temporary Measures to Stimulate Employment: An Evaluation of Alternatives,* 1975.

TABLE 1—UNEMPLOYMENT RATES BY RACE, SEX AND AGE DURING THE CURRENT RECESSION

| Demographic Group | Unemployment Rate[b] (in percent) 1973–IV | Unemployment Rate[b] (in percent) 1975–III | Jobless Rate[c] (in percent) 1975–III |
|---|---|---|---|
| All | 4.7 | 8.4 | 9.5 |
| Adult males | 3.1 | 6.9 | |
| White | 2.8 | 6.4 | NC[d] |
| Nonwhite[a] | 5.4 | 11.5 | |
| Adult females | 4.7 | 7.7 | |
| White | 4.2 | 7.0 | NC |
| Nonwhite[a] | 8.1 | 11.8 | |
| Teen-agers (16–19) | 14.3 | 19.8 | NC |
| White | 12.8 | 18.0 | |
| Nonwhite[a] | 28.3 | 36.0 | |
| All whites | 4.3 | 7.7 | 8.7 |
| All nonwhites | 8.6 | 13.8 | 16.4 |

[c] Defined for each demographic grouping as the unemployed plus discouraged workers divided by the labor force plus discouraged workers.

[d] Not computed.

pansion, when the rate for adult white males tends to be explained completely by frictional unemployment, and highest at or near the trough of the business cycle. In the current cycle, the overall gap in unemployment rates has widened from 4.3 percentage points in 1973–IV to 6.1 in 1975–III. The gap of 6.1 in 1975–III would widen to 7.7 percentage points with the inclusion of discouraged workers, and would be even larger with further adjustments for including the underemployed. With the inclusion of the discouraged worker (Table 1) but not the underemployed, the jobless rates in 1975–III were 8.7 percent for whites, as compared to 16.4 percent for blacks.

The pattern of the racial gap over the last two decades has also varied by sex and age. For adult males (aged 20 and over), while unemployment rates for whites have varied between 6.6 and 1.8 percent, those for blacks have ranged from 13.9 to 3.6 percent. The resulting gap for adult males has fluctuated between 7.8 and 1.6 percentage points.
